### MENTAL TESTS.*

By CHARLES L. DANA, M.D.,

NEW YORK.

PROFESSOR OF NERVOUS DISEASES, CORNELL UNIVERSITY MEDICAL COLLEGE.

By intelligence or mental ability we mean the effective activities of the mind. It is ordinarily tested in the process of education by the school grade; later in life by the efficiency of the person's career. It implies a retentive memory, readiness to recall, an easy play of associations formed by past experiences, the ability to combine the material of the mind into a coherent and effective whole, *i.e.* to initiate, complete, imagine, or invent.

An intelligent mind does not require more than average esthetic feelings, and it may not require the ordinary normal moral feelings though both are present in the highest intelligence.

Mental tests are used to measure all the activities of the mind. Thus we have tests for memory, for attention, perception, and for association. A mental test is not necessarily an intelligence test for a man may have a good memory, quick perceptions, and an inferior intelligence. Intelligence tests include to a degree tests for these special faculties, but at the same time and especially a test for the power of combining and coordinating, as when one interprets a picture or a fable, or completes a fragmentary sentence.

Most mental and intelligence tests are quantitative in character. They show how active and alert the mind is in its working. One form of test, however, especially shows what is the content of the mind, and its tendencies and trends. This is the association test.

Methods of testing intelligence have been in use in psychological laboratories for over twenty-five years. Their employment has gradually extended to the physiological laboratory, to the workers in psychiatry, and to the students of education and child development. The work was first begun in the interest of psychological science almost entirely, and was next and quite early applied to educational problems.

It was at an early stage of the work, about fifteen years ago, that in conjunction with Prof. J. McK. Cattell, I drew up a scheme of mental tests for use in psychiatry. It was prepared in the form of a case-record with illustrative tests for attention, perception, memory, association, etc. This original work, though crude as compared with the tests of to-day, has the merit of being the first, I think, of its kind. At any rate, it interested me in the subject of such tests and I have kept in touch with the progress of the work since that time.

*Read at a meeting of the Practitioners' Society of New York, Nov. 1, 1912.

During the last ten years these tests have developed in three ways. We have first, the elaborate technical tests which belong to the psychological laboratory and which have to do with contributions to the science of psychology and incidentally to educational problems. Second, we have the so-called "association tests" which have been worked out by Jung and those of his school. These tests in connection with psychanalysis bring out the content of the mind and give us some knowledge of subconscious states. Third, we have the so-called "Binet-Simon tests." These last are not so much for the purpose of measuring intelligence as for marking the development of the child's mind.

The plain man who does not know or pretend to be able to know anything about psychology, understands, at least, this: that when a patient is before him he expects to find out whether this patient is listening to him and understands him, whether he remembers well what he is told, and what he has been doing. He expects to find out what sort of thoughts and feelings are in the patient's mind, and whether he expresses himself effectively to the doctor to whom he is talking. These things simply mean that we study the powers of attention and perception, the memory, the power of comprehension and association, so as to understand and carry out things that are told to him; the emotional state and the intellectual equipment. These are the main lines along which mental tests are developed.

I propose briefly to speak of the three groups of tests, giving some details about each and indicating the uses which physicians and educators will find for them in their different fields of activity.

**The Laboratory Tests.**—The laboratory tests have been worked out by a large number of investigators during the last thirty years. In 1898 their application in mental diseases was presented in an elaborate textbook on the subject by Prof. R. Sommer, and later much work was done with them by Kraepelin and others. Their application in the psychological laboratory has been going on continuously in many places and by many observers.

A compilation of these tests together with original work of his own, has been made by Dr. Guy N. Whipple, in a book entitled "Manual of Mental and Physical Tests," 1910. Leaving out the preliminary tests which have to do with the physical, motor, and sensory capacities, his tests are grouped under seven headings: (1) Attention and perception; (2) Description and report; (3) Association, learning, and memory; (4) Suggestibility; (5) Imagination and invention; (6) Intellectual equipment; (7) Developmental tests.

This classification is somewhat arbitrary as every classification must be. The series of tests which I have arranged is made up from those of our original record, from Whipple's work and from Ziehen's series of tests, which last include several special tests devised by different psychologists.

These tests may be used by those who wish to investigate the psychic make-up of the patient, whether it be for purposes of studying character, development, or disease. Very often it is necessary, or it may be useful to use only two or three of the tests.

For example, in certain diseases like Korsakoff's psychosis we are especially interested in memory defect.

In hysterical and psychasthenic conditions, the association test is especially used.

In determining whether the patient is developing some form of dementia, or in testing his general mental capacity, the test for imagination and invention and the test for abstract ideas are useful.

As a basis for all tests a study of the intellectual equipment is indicated.

Ethical and esthetic tests are of importance in studying the character and make-up of children and adults and in determining the presence of mental deterioration.

A simple test for esthetics is used as a routine in studying the development of the child's mind. Any elaborate test is only needed in cases where we wish to discover also the intellectual equipment and emotional and idealistic tendencies of the patient.

In giving tests it is always important to explain carefully to the patient what the object of the test is and what he is expected to do. In some of the tests a stopwatch must be used and the time noted.

The following gives in a tabular form the general character of the mental tests:

| *Mental functions tested.* | *Method.* |
|---|---|
| I. Attention and perception. | Bourdon test. |
| II. Memory: | Personal history. |
| Old impressions, | Repetition of numbers, etc. |
| New impressions, | Reproduction of picture. |
| Rote memory, | Repetition of a story. |
| Logical memory. | Pair-words. |
| | Marie test. |
| III. Association, controlled and free. | Replying to stimulus words. |
| | Analysis. |
| | Dreams. |
| IV. Intelligence: | |
| Imagination, | Ebbinghaus test. |
| Invention, | Masselon test. |
| Combining, | Proverbs, fables. |
| Orientation, | Arithmetical test. |
| Ideation, | |
| Judgment. | Specification of the class to which an individual belongs. |
| V. Abstract Ideas. | Generalization. |
| | Definition. |
| | Differentiation, etc. |
| VI. Intellectual Equipment. | Vocabulary. |
| | School-knowledge. |
| | Range of information. |
| VII. Emotional State. | Effect of seeing picture. |
| | Hearing a story. |
| VIII. Ethical. | Pictures, questions. |
| IX. Esthetic. | Pictures, questions. |

I. *Attention and Perception.*—Go over the whole and strike out one of the letters, *e.g.* the letter D. Measure time; note mistakes. It should be done in 30 to 40 seconds.

II. *Memory.*—In testing for memory, we test for old impressions and new impressions. The test for new impressions is termed "immediate memory." It is these two forms of memory or revival which are most important for physicians and psychologists to study.

We also make tests for "rote memory," that is to say, for series of discrete and unrelated impressions, such as letters, digits, and unrelated words; and tests for logical memory in which the material is presented in a logically connected whole; so that the association helps one in revival of the words desired. In testing for old impressions we generally test simply for logical or associative memory. In testing for new impressions we usually test for rote memory.

The tests of memory almost always involve also a testing for association, and the tests for association, learning, and memory are grouped together by Whipple.

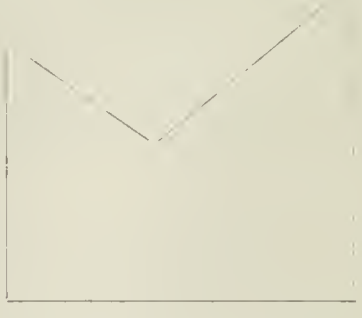
The following tests are mainly taken from Ziehen:

(1) Old Impressions: These are tested by questioning the patient as to his personal and family history, school knowledge, etc. (Logical memory).

(2) New Impressions: (*a*) Repetition of numbers and letters; for instance, 1869, 79581, 834596, 41927561. An ordinary individual can repeat without difficulty six numbers; the *Korsakoffs* usually can retain three numbers; paretics repeat four numbers. Inability to repeat three numbers usually indicates a grave intellectual defect or disassociation. Name the numbers in an even voice without rhythm or accent. Test visual memory by showing the numbers printed on a card. (Rote memory).

(*b*) Repetition of an example, which is given at the beginning of the seance.

(*c*) Reproduction of objects, colors, or pictures. The following figure is usually exposed for fifteen seconds; later covered for fifteen seconds and then patient is asked to reproduce it.



(*d*) Reading and relating of a short story which has definite point, *e.g.*: The steamship Gate City of the Ocean Steamship Line, bound from Savannah to Boston, went on the outer bar three miles east of the Life Saving Station at 9 o'clock to-night. The Gate City had on board forty-nine persons, three of whom were women. There was a dense fog at the time, but the ship was finally saved.

(*e*) Pair-words, which usually have some relation to each other, are given to the patient. After a pause, a member of the pair words is named and the patient is requested to reproduce the corresponding one.

Garden—large.
House—small.
House—yellow.

Picture—nice.
Dress—white.

A very good test for new impressions, rote memory, attention, and association is one used by Mr. Ellis of the New York Neurological Institute. The patient is given a pad of paper and pencil and then ten numbers of six figures each are given to him verbally, to write down and add up. See association tests.

III. *Association Tests.*—These tests when fully carried out involve all the machinery of the modern methods of association tests coupled with psychanalysis. They involve a large amount of time and mean an almost entirely specialized piece of work. There are two forms of tests, one in which the association is controlled by giving the subject definite test words; the other, a free or running association, in which the associations are started but not guided. Both forms of tests are used in psychanalysis, and in psychotherapeutics. They are not used as intelligence tests, but as a means of learning the content of the mind. They show "whether a subject has a tendency to take things with peculiarly personal reference or exaggerated self-consciousness, or to diagnose disturbing trends of thought." (Wells).

Briefly the test is as follows:

A list of 70 or 100 words is made out; the experimenter with a stopwatch gives out these words and the subject answers as quickly as possible some word which comes to his mind. The word itself named by the subject is written down and the time of the response noted. The average response for a normal individual is about one and one-half seconds. Every now and then, however, there occur more rapid or delayed responses. The delayed responses are more or less definitely connected with some emotional state or complex either conscious or unconscious.

The test is repeated, then the words connected with the delayed responses are brought together and the subject questioned as to their significance and the ideas and emotional states that underlay the retardation are discovered.

There are standard lists of words, but these are much varied for inividual cases, hence I append no full list here.

Ziehen employs the following short list of fifteen words:

| | | | | |
|---|---|---|---|---|
| Forest, | Disease, | Sin, | Sweet, | Run, |
| Red, | Small, | Father, | Poison, | Death, |
| House, | City, | Jealousy, | Wedding, | Fish. |

At the end of the seance the first three are repeated. After twenty-four hours and one week, respectively, the other words are repeated. This makes of it to some extent an intelligence test, as it involves memory and association.

The tests for *controlled association* which may be used as intelligence tests are 1, the part-whole test; 2, the genus-species test; 3, the opposite test.

Give as quickly as possible the name of the whole of which the test word is a part:

1. Part-Whole Test.

| | | | | |
|---|---|---|---|---|
| Door, | Letter, | Button, | Cover, | Engine, |
| Pillow, | Leaf, | Nose, | Page, | Glass, |

2. Genus-Species.

Animal, Trees, etc., etc.

3. Opposites-Test.

| | | | | |
|---|---|---|---|---|
| Bad, | Little, | Sad, | Well, | Peace, |
| Inside, | Soft, | True, | Sorry, | Few, |
| Slow, | Black, | Dislike, | Thick, | Below, |
| Short, | Dark, | Poor, | Full, | Enemy. |

*Free Association Tests.*—The subject is given a pencil and a pad of paper and is told to write as fast as possible as many words as come into his mind in a certain fixed period of time.

In connection with the subject of association or with the tests for association there are certain supplementary tests used. These consist in the addition, multiplication, or subtraction of various sets of figures. The experimenter notes the time and the accuracy with which the work is done. These tests are more especially used for determining the question of fatigue or work capacity of the patient. They are not very useful as tests of intelligence.

The following is an example of material used in a computation test:

957996
869675
326872
847991
959769
347978
978643
989455
878244
687927
798672
888961
977450
397995
489707
890438
673543
546281
911764
902549

These figures are read out to the subject who puts them down and adds them. Note time, accuracy, continuity of attention, motor dexterity. It has been found that speed and accuracy as a rule are in inverse ratio. The better work the less speed.

IV. *Imagination and Invention* (Combinative Activities).—Under this head Whipple gives a number of tests which are placed by Ziehen under the head of combinative activities.

Ebinghaus Test.—Mental ability or intelligence demands not only ready memory, quick and easy association but the ability to combine into a coherent whole independent and seemingly contradictory impressions, says Ebinghaus. Intelligence is a combinative activity. To measure intelligence then, Ebinghaus prepared mutilated prose, by eliding letters, syllables, and phrases. This he considers a real test of intelligence. Whipple places the test under the head of imagination and invention tests. When fully carried out two or three specimens are given of mutilated prose. Time and accuracy are noted. The test needs to be standardized for practical use outside a laboratory. A simple example of the test is the folowing:

Supply missing words or syllables in the following: There was — — merchant — — had — child; — barely laden — then making — — upon —, in — he had — all — wealth, in — hope — making — great — when — news — that — were lost.

This test in a still simpler form was used by Cattell in our Case Record as a test for association.

Word-building Test.—Arrange the letters so as to make 3 words:

A T H
I V W E
O E H S R

Time in seconds.....

Rearrange the words so as to make a sentence:
Winds cold and the north disagreeable are
Time in seconds.....

While word-building is an intelligence test, it is not a very good one. About all that can be said is that bright persons do it better than stupid ones.

Definition Test.—What is a fork? What is a table? What is a chair? What is a horse? What is a mother?

The definitions are not given in terms of *use* by subjects above the mental age of nine. The tendency to define by use shows retardation or a dementing tendency in adults.

Masselon Test.—Formation of sentences out of two or more words:

Cat—mouse—cellar.

Hunter—fix—woods.

Children of the age of eleven can do this in one minute.

Proverbs and Fables.—The subject is asked to explain the meaning of certain proverbs and fables.

Strike while the iron is hot.

Many cooks spoil the broth.

Do not look a gift horse in the mouth.

Fable of dog in the manger.

Arithmetical Test.

X + 25 equals 40; what is X?
X — 15 equals 50; what is X?
X × 5 equals 45; what is X?
X ÷ 9 equals 7; what is X?

Backward Association.—Enumeration backwards of week days and of months; counting from 20 to 1, etc. Children of the age of eight can do this.

Besides these specific tests, questions may be asked to determine whether the subject shows orientation and grasp on new environment, and whether he can explain the meaning of certain pictures.

V. *Tests for Abstract Ideas.*—Tests of this kind are more particularly of use in determining the degree of mental development and grade of intelligence.

The following are Ziehen's tests. Many of them are in the Binet-Simon list, where Whipple discusses them.

The tests are divided into four parts:

1. Specification and generalization.
2. Definition.
3. Differentiation.
4. Exemplification.

(1*a*) Specification:

To what class of the animal kingdom do the following belong: eagle, ant, goose, chicken, turkey?

Name animals which have wings, bill and lay eggs, etc.

(1*b*) Generalization:

Name different kinds of birds.

Name different kinds of trees.

Name different kinds of governments.

Name different kinds of instruments.

(2) Definition:

What is jealousy?

What is gratitude?

What is hatred?

What is a butterfly?

What is a horse?

(3) Differentiation:

Differentiate between an ox and a horse; child —dwarf; bird—butterfly; ladder—steps; lie —mistake; avarice—economy; box—basket.

(4) Exemplification:

What is worse, lie or mistake, and why?

Give an example of gratitude? Jealousy? Avarice? Envy?

The lack of ability to do at least three-fifths of these tests would put one below the mental age of fifteen making proper allowances for educational disadvantages.

VI. *Intellectual Equipment.*—The psychological laboratories use very elaborate tests for determining the vocabulary (Kirkpatrick test) and range of information (Whipple test).

In ordinary cases all that we need are some facts regarding the patient's school knowledge.

School Knowledge:

1. Name some of the presidents of the United States.
2. Give the name of your state and its capital.
3. Tell me the name of some of the high mountain ranges in the United States.
4. What is the largest river in the country?
5. Can you tell me what an island is?
6. Can you tell me what month in the year has the fewest number of days?
7. Tell me the names of the months.
8. Tell me the names of the colors in the rainbow, or spectrum, as it is called.

VII. *Ethical and Esthetic Tests.*—No very definitive or absolute tests can be outlined. The ethical reactions have to be determined by direct questions, by knowledge of the patient's life; and perhaps in the case of children and simple minds to reactions to certain pictures and stories. (See Binet-Simon tests.)

The following tests are fairly accurate for educated Americans:

Esthetics, Literary.—A person who has read and not felt touched by the art in any of the following writings, may be considered absolutely deficient in literary esthetics:

Keats—Ode on a Grecian Urn: Opening passages of Endymion.

Shelley—Skylark.

Milton—Passages from Paradise Lost; Lycidas.

Wordsworth—Ode to Immortality; Tintern Abbey.

Pater—Marius, the Epicurean.

Bible—Job, Chap. 98.

Johnson—Rasselas.

Esthetics, Musical.—Education and opportunity being the same, the person's musical feeling may be gauged by his real appreciation of first rank musicians; or second rank or the ranks *below.*

| First Class | Second Class | Third Class and Lower. |
|---|---|---|
| Palestrina | Berlioz | |
| Bach | Rubinstein | |
| Haydn | Gounod | |
| Gluck | Mendelssohn | |
| Mozart | Strauss | |
| Beethoven | Offenbach | |
| Schumann | Weber | |
| Schubert | Thomas | |

| First Class | Second Class | Third Class and Lower. |
|---|---|---|
| Fraunz | Bizet | |
| Chopin | Mollecker | |
| Wagner | Sullivan | |
| Brahms | | |

*Results of Laboratory Tests.*—It may be asked now what results of practical value have been obtained from the various elaborate tests of the psychological laboratories. In reply one may say that many important facts have been brought out pertaining to the relative intelligence of the male and female, to mental development, to the power of work, and to questions relating to education, generally.

Thus, Whipple states among other things "that logical memory is twenty-five times as good as rote memory and is better in girls than in boys; that memory power gradually increases up to the time of puberty and is often at its best from the twelfth to fifteenth year."

Association tests show that in association experiments, women select words which indicate things ornamental, individual, and concrete; men, things more remote, instructive, useful, general, and abstract (Jastrow).

The computation tests show that feelings of fatigue are not a measure of mental inability. The disinclination to work does not signify inability to work. The invariable need of vacations has been put in doubt.

The sex differences shown by these tests indicate that in range of information boys and men exceed girls and women; that in reporting and description men are more correct than women; that in word building boys are better than girls; that in vocabulary they are equal, and that in imagination and invention they are equal; in nearly all other tests the female sex is better than the male, namely, in suggestibility, in rote memory and logical memory; in association activity and in computation the difference is not very great. These tests have been made, however, so far as I can learn, mostly upon pupils in schools and colleges.

The question of mental fatigue under all kinds of conditions has been specially studied by means of the laboratory tests.

Some observers find that mental work is done best when interrupted with intervals of rest of two or three hours. It is poor in the evening after a day's labor. School work has been found to be a little better in the middle of the afternoon and not so good at the end of the day, though one experimenter has denied this.

I am not trying to sum up all that laboratory methods have contributed to the practical side of education or psychology; but I am indicating some of the lines upon which results have been formulated.

While the laboratory and the Binet-Simon tests aim to measure the development and powers of the mind, the association and analytic tests aim to find out also what is in the mind. They tell how the mind reacts and why. The methods employed are by controlled association, free association (verbal and mental catharsis), and by dream analysis. The technique is given under the laboratory tests. The whole process may be used as a very intensive form of retrospection, introspection, and re-education. It is when fully carried out a research into and recall of the past conscious life. Naturally this is sometimes dangerous and perhaps often futile.

But the methods may be used with benefit, and without danger in diagnosis. Here in particular the association test without elaborate analysis is employed.

In the last year or two judgment as to the value of test association has been somewhat changed.

In the monograph on association tests by Hunt and Rosanoff, association tests were made upon 1,000 normal persons and a great number of the insane. After some experimenting these investigators gave up the attempt to utilize the retardation time and contented themselves with simply studying the associations themselves.

Dr. Rosanoff, in a personal letter to me, states that "Much evidence was gradually accumulated to show that retardation of responses may be due, even in the same subject at different times, to a great variety of causes. I am not inclined to dispute that among these causes there is occasionally—perhaps frequently—to be found some emotional attuning aroused by the stimulus word; but I do not think the association test in any form could be relied on for trustworthy results in refined psychanalysis. For a psychologist to accept a finding, so omnisignificant as delay of response, for an indication of anything definite is, in my opinion, as much open to criticism as it would be for a chemist to judge by mere gross weight of a lump of iron ore the amount of iron that it contains, or for him to say that the entire weight is due to iron."

However, in association experiments there are many other things than retardation which give characteristics to the subject's responses, and I believe that there is practical value in the use of the test in diagnosis.

Recently a patient was sent to me with apparently a clear-cut history of epilepsy lasting for four years. The description of the symptoms of her psychosis corresponded with those of typical haut mal and petit mal attacks. There was, however, something in the character and mentality of the patient which led me to suspect that it was not a constitutional or degenerative, but an episodic neurosis and perhaps a psychogenic neurosis. In other words, that perhaps the convulsions were functional and due to some morbid mental state accidentally engrafted rather than to a deep-seated degenerative process going on in the cortex.

I therefore sent her to a psychoanalyst, Dr. H. W. Frinck, whose comments are as follows:

"It seems to me that there is not the slightest doubt that the girl has pathological complexes and is decidedly neurotic. The test is typically hysterical and is not at all like the typical test of an epileptic, but this does not prove anything as to the nature of the fits themselves, though it is somewhat suggestive."

"The sadistic or hate complex which she appears to have is the one usually found at the bottom of hysterical epileptoid attacks."

This is an example of the kind of cases in which mental tests will eventually be a solid help. Just now we are feeling our way.

So far as I can learn at present there is only one disease in which the associations and dreams furnish diagnostic evidence and that is dementia præcox, where the associations are almost all internal and the dreams are said to be of peculiar and chaotic character.

I believe it will be found that the association processes develop in the group know as the "hysterical" and "psychasthenic" in a somewhat peculiar

way; but the data cannot yet be used for anything more than confirmation of diagnosis.

A further use of psychanalyses and association tests is claimed by Jung. He states that persons who have themselves analyzed and their associations properly adjusted feel a surer grip upon themselves and will not have any neuroses or psychoses; if they are thus re-educated. This is a field of prophylaxis which certainly is interesting if true.

**Tests of Mental Development—the Binet-Simon Tests.**—About three years ago I asked a good many of my medical and even neurological friends if they had used the Binet tests and only one was familiar with the word.

Within the last three years, however, these tests have jumped into tremendous prominence and have been widely and generally accepted as valuable helps in measuring the development of the growing mind.

I must apologize now for attempting to say anything upon the subject, but the question of retardation is in the air. It is announced, and to a certain extent demonstrated, that a large number of criminals, defectives, and epileptics are not bad, so much as they are backward and that an enormous amount of the evil conduct of to-day is due to retardation rather than to an intelligent pursuit of crime.

We are preparing to sift out more of the retarded from our public schools and to place them under properly qualified teachers. We are planning to have delinquent children and juvenile criminals put through Binet tests and expect to show that their actions are often the result of stupidity and lack of intelligence, and that they should be treated on that basis rather than punished for wilful crime.

The immigrants who are poured upon our shores at the rate of a million a year, show a large percentage of this class. It is to be hoped that this undesirable minority will be sifted out. It has been found that this class of the retarded are prolific; that they intermarry or breed among themselves and produce a new species of constitutionally inferior human beings.

Thus there is a new and prodigious problem before this country in our study and management of this class. It is related closely to the subject of eugenics, which is interesting the public mind most deeply just now.

I have found in, perhaps, not very extensive investigation that what are called the minor psychoses occur to an extent among a retarded class of individuals.

Many years ago one of our eminent and beloved members, now deceased, Dr. Shrady, was discussing with me the subject of writer's cramp. He did an enormous amount of writing himself, refusing generally the aid of a stenographer. I said to him one day, "Aren't you afraid you will have a professional cramp?" He smiled and tapped his head with his finger. "No," he said, "I haven't that kind of a brain." The inference was simply that people with a very good brain did not get such neuroses. This is true.

Professional cramps, however, are not the cases in which I have looked for retardation. Many cases of so-called hysteria, psychasthenia and even of neurasthenia; also of mild recurrent melancholia occur in persons who have not a strong intelligence.

In going over a list of 100 cases of neurasthenic and psychasthenic origin I would estimate that at least 50 per cent. of them were not constitutionally smart.

Taking up the matter in a laboratory way, I have already made further confirmatory tests of psychasthenic cases and applied to them the Binet-Simon scale. Now, according to this scale, if a child tests up to or above the age of twelve, he is normal and does not require any custodial care; he goes out into the world and tries, at least, to make a way for himself. If a woman she may marry. If a man he may undertake an art, a craft, a business, or a profession. These people, perhaps have no moral instability and do not become criminal; but yet, being really retarded, instead of filling the ranks of criminals and the work-house population, they fill the offices of the neurologists with their sufferings and complaints.

The study of retardation, therefore, among the psychoneuroses furnishes a rich field for further investigation.

The Binet-Simon test first appeared in 1905. It was used, and experimented with, some changes made, and the final corrected scale was published in April, 1911.

It is now possible by means of this scale to determine fairly well the mental age of children. There will be much less indefiniteness regarding the terms used indicating the feeble-minded.

Thus, the term "idiot," which is technically restricted to those who cannot talk, corresponds to the mental age of one and two years.

The term "imbecile," which includes persons who understand spoken language and talk with varying degrees of fluency, corresponds to the mental age of three, four, five, six, and seven years.

The moron is one who, in addition to using spoken language, is capable of learning to read and write, and he corresponds to the mental age of eight, nine, ten, and eleven years.

The feeble-minded are persons who include all three groups and correspond then to the mental age of from one to twelve years. A person having the mental age of twelve may be retarded, but is not feeble-minded, and technically the retarded would be persons who have the mental age of twelve to fifteen years and who do not get beyond it.

I would like to add as a comment upon the Binet-Simon tests some criticisms which have been furnished me by Mr. Frederick W. Ellis, psychologist to the New York Neurological Institute.

Mr. Ellis states that "The Binet-Simon tests have been in use at the Clinic of the Neurological Institute for over two years as an auxiliary to the neurological examinations. These tests do not claim to give an estimate of the degree of native power of the mind, but only of the capacity of the mind for acquiring simple knowledge at various degrees of maturity. They do not estimate such special functions of the mind as attention, perception, memory, and power of association, but deal rather with such general capacities as power of interest, good sense in comprehension, useful judgment, capacity to initiate, and adaptability to circumstances. It is on points such as these, and not on general ability, that the recognition of normality of mind must rest whether the estimate is being made in the physician's office, the clinic, the school room, or in the general walks of life."

Mr. Ellis has advised five supplementary tests. These are as follows:

1. The making of as many crosses in a 4½-inch square as can be made in two minutes.

2. The pegging of a 100-hole board in the shortest possible time.

These two tests supplement each other and give valuable information on the power to coordinate and sustain interest.

3. The immediate recall in order of a set of ten familiar objects.

4. The association of these objects in groups according to their common qualities.

5. The interpretation of simple pictures to test the imagination and general comprehension.

When the mental age has been determined by the Binet-Simon scale this further inquiry is made into the functional capacity of the subject, and many facts of differential value between individuals come to light.

## APPENDIX.

### THE BINET-SIMON TESTS ARRANGED IN AGE AND DIAGNOSTIC GROUPS FOR CONVENIENCE IN CONDUCTING EXAMINATIONS, AS FINALLY FORMULATED IN 1911.

#### IDIOTS.

Mental Age 1 and 2 Years.

1. Move lighted match slowly before child's eyes. *Full credit given if eyes follow light for briefest period.*

2. Place a wooden block in child's hand. *Credit given if block is grasped.*

3. Show the wooden block without touching child with it and say, "This is for you, don't you want it to play with?" *Credit given if child takes it.*

4. Offer child a piece of wood and a piece of chocolate of the same size. *Credit given if he eats the chocolate and does not attempt to eat the wood.*

5. Show child a piece of chocolate, then wrap it in paper and present it to him, telling him to eat it. *Credit given if he removes the paper before eating.*

6. Make simple movements, clapping the hands, sitting down, standing up, etc., and tell child to do the same. *Credit given if one intention is accomplished.*

Fig. 1.

#### IMBECILES.

Mental Age 3 Years.

7. Show me your nose. Show me your eyes. Show me your mouth.

8. Listen well and repeat what I say. 4; 3—7; 6—4; 5—8. Pronounce numbers slowly and distinctly with one-half second interval between, one pair at a time. *Full credit given for one exact repetition.*

9. Place Picture 1 before child and ask, "What is that?" or "What do you see there?" Follow this by Pictures 2 and 3. (Figures 1, 2, 3.) *Full credit given if some objects are enumerated.*

Fig. 2.

10. "What is your name?" If first name only is given—"And your other name?"
*Surname required.*

11. "Listen well and repeat what I say: I am cold and hungry." *No errors of any kind allowed.*

Mental Age 4 Years.

12. "Are you a little boy or a little girl?" If necessary—"Are you a little girl?" "Are you a little boy?"

13. Show child a penknife, saying, "What is that? What is it called?" Then show penny and finally key, asking same questions. *Names of three objects required.*

14. "Listen well and repeat what I say. 4—9—2; 3—7—4; 5—8—1." *Full credit given for one exact repetition.*

15. "You see these two lines. Tell me which is the longer." (Figure 12.)

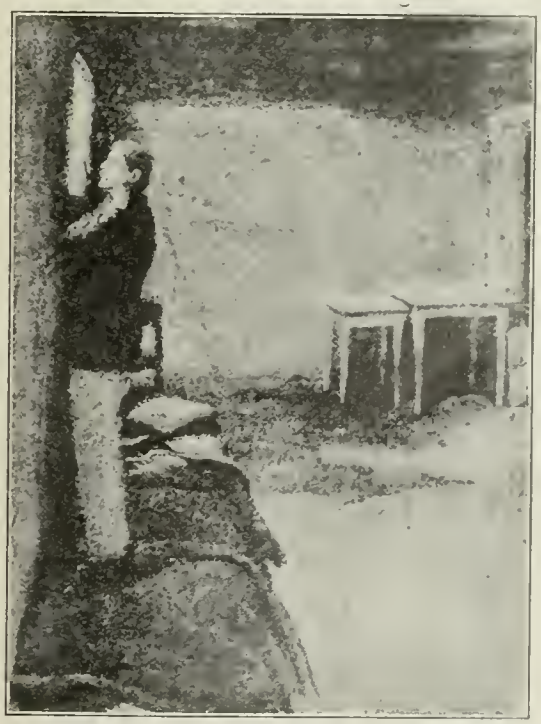

Fig. 3.

Mental Age 5 Years.

16. Place two boxes weighing 3 and 12 grams respectively on the table before the child, leaving a space of 5 or 6 centimeters between them, and say, "You see these two boxes? Tell me which is the heavier." Repeat, using boxes weighing 6 and 15 grams, and repeat again, using first pair.

*If there is still doubt about the child's ability to compare weights, repeat process.*

17. Draw a square 3 to 4 centimeters in diameter with ink and ask the child to copy it, giving him pen and ink to do so.

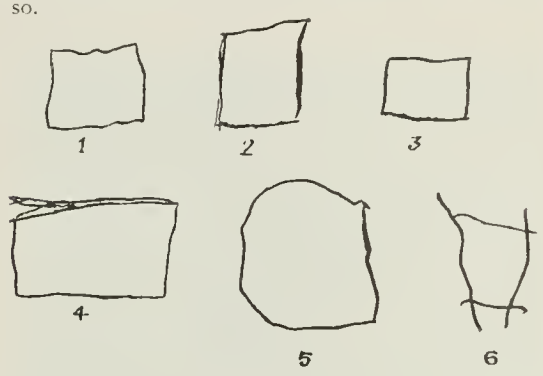

Fig. 4.

18. "Listen well and repeat what I say: My name is Charley. O! the naughty dog."

19. Place four pennies in a row before the child and say, "Do you see these pennies? Count them and tell me how many there are."

*Child is required to point to each with finger, no error allowed.*

20. Place an oblong card on the table before the child and place also, nearer to the child, two triangular cards formed by cutting another card like the first one in two, along a diagonal. Place these two triangular cards in such position that their hypothenuses form a right angle one with the other, then say to the child, "Put these two pieces together so that they will form one card like this," (indicating the oblong card). If the child turns over one triangular piece without noticing it, it is permissible to begin again.

Mental Age 6 Years.

21. "Is it morning now?" "Is it afternoon?"

22. "What is a fork?" "What is a table?" "What is a chair?" "What is a horse?" "What is a mama?"

*If some use of three of the objects is mentioned the response is considered correct.*

23. Draw a diamond figure with ink and ask the child to copy it, giving him pen and ink for the purpose.

24. Place 13 pennies in a row on the table before the child and say, "Count these pennies for me, pointing to each one as you count it."

25. Show pictures of faces (Figure 6). Expose first the upper two alone, next the two middle ones, and last the lower ones, saying each time, "Which is the prettier of these two faces?" *No error allowed.*

Mental Age 7 Years.

26. "Show me your right hand." "Show me your left ear." *No error allowed.*

27. Show pictures as in Test 9, requiring descriptions.

28. "Take this key and put it on that chair, bring me that book lying on the table and open the door." *Repeat these directions distinctly twice.*

29. Place three two cent and three one cent stamps on the table before the child. Make sure that he knows the

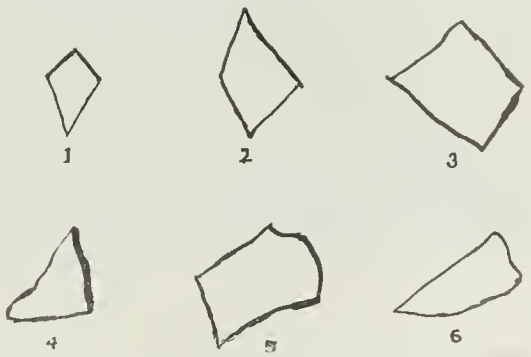

Fig. 5.

2's from the 1's and then ask him to count how much they would all cost.

30. Have four pieces of colored paper, red, blue, yellow, and green. Point to each, asking, "What is this color?" *No error allowed.*

MORONS.

Mental Age 8 Years.

31. (a) "Do you know what paper is?" "Do you know what cardboard is?" "Are they alike?" "In what way are they not alike?"

Fig. 6.

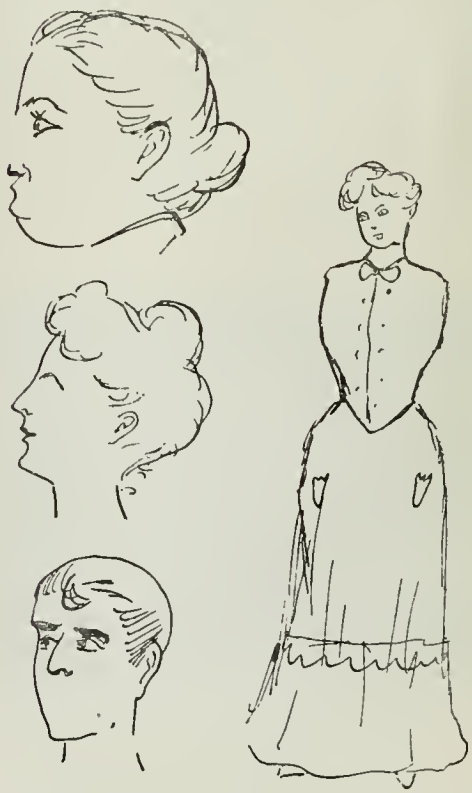

Fig. 7.

(b) "Have you ever seen a fly?" "Have you ever seen a butterfly?" "Are they alike?" "In what way are they not alike?"

(c) "Do you know wood when you see it?" "Do you

know glass when you see it?" "Are they alike?" "In what way are they not alike?" *Two satisfactory answers required.*

32. "I want you to count backward from 20 to 0. Like this—20—19—18." *This must be accomplished in 20 seconds. One error allowed.*

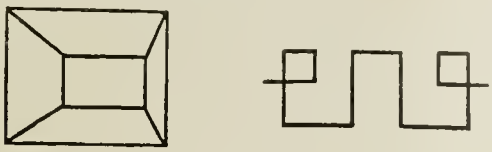

Fig. 8.

33. The four pictures in Figure 7 are shown one at a time and the question asked with each, "What is missing in this picture?" *Three correct replies required.*

34. "What day is to-day? "What date is it?"

35. "Listen well and repeat what I say: 3-8-5-7-1; 9-2-7-3-6; and 5-1-8-3-9." *One group given at a time. One exact response required.*

Mental Age 9 Years.

36. In a pile before the child place the following coins: Ten pennies, two nickels, two dimes, one quarter, one half dollar. Then propose a game of storekeeping, the child to keep the store and use the pile of money to make change, the experimenter to be the customer. Add some articles for sale. Then buy something for four cents. Give the child a quarter and require the change.

37. Test No. 22. Definitions superior to use are required.

For an the
at hour early
we country started.

To asked exercise
my I teacher
correct my

A defends
dog good his
master bravely.

Fig. 9.

38. Show the child successively a penny, a dime, a dollar, a quarter, a nickel, a half dollar, a two dollar bill, a ten dollar bill, a five dollar bill. Ask, "What is this?" with each.

39. Name the months of the year in order. *One error allowed, time 15 seconds.*

40. (a) "If you were going away and missed your train, what would you do?"

(b) "If one of the boys should hit you without meaning to, what would you do about it?"

(c) "If you broke something belonging to some one else, what would you do about it?" *Two good responses required.*

Mental Age 10 Years.

41. Place on the table before the child five boxes weighing 3, 6, 9, 12 and 15 grams respectively. Say to him, "These little boxes all weigh different amounts. Some are heavier and some lighter. I want you to place the heaviest here and by its side the one which is a little less heavy, and then the one a little less heavy and the one still a little less heavy, and finally here the lightest." *Three trials made, the boxes mixed after each. Two successes in three are required.*

42. "I am going to show you two drawings and after you have looked at them I shall take them away and ask

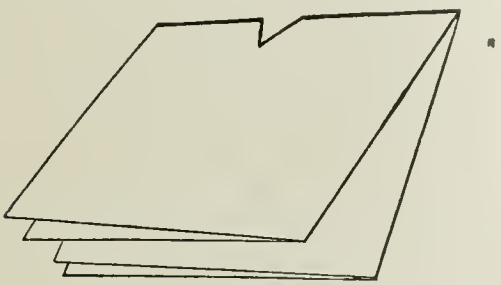

Fig. 10.

you to draw them from memory. You must look at them closely because you will only have them for ten seconds and this is a very short time." (Drawings shown in Figure 8.)

*Full credit is given if the whole of one drawing and half of the other is reproduced exactly.*

43. "I am going to read you some sentences; in each one of them there is something foolish or absurd. You listen carefully and tell me each time what it is that is foolish."

(a) "An unlucky bicycle rider fell on his head and was instantly killed; they took him to the hospital and fear

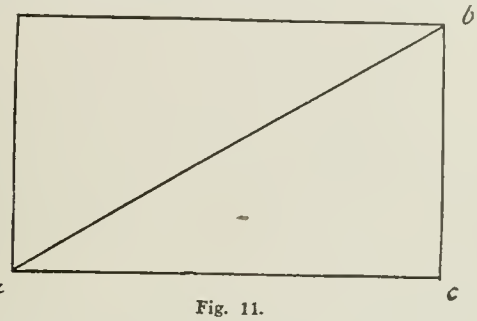

Fig. 11.

that he cannot get well."—After a pause—"What is foolish in that?"

(b) "I have three brothers, Paul, Ernest, and myself"—"What is foolish in that?"

(c) "The body of a young girl cut into 18 pieces was found yesterday. People think that she killed herself."—"What is foolish in that?"

(d) "There was a railroad accident yesterday, but not a serious one, only 48 persons were killed"—"What is foolish in that?"

(e) "A man said: 'If I should ever grow desperate and kill myself I should not use Friday for the purpose because Friday is an unlucky day and might bring me unhappiness.'"—"What is foolish in that?"

*Correct solution of three of the five statements required.*

Fig. 12.

44. (a) "If you were delayed on your way to school, what would you do about it?"

(b) "Before taking part in something very important, what would you do?"

(c) "Why do we more easily pardon a bad act done in anger than a bad one done without anger?"

(d) "If some one should ask your opinion of one whom you did not know very well, what would you say?"

(e) "Why should we judge a person by his acts rather than by his words?"

*Two errors allowed.*

45. Write the words *Paris, fortune, stream.* Show them to the child, reading them to him several times. Then give him pen and ink and tell him to write a sentence containing all three of these words.

Fig. 13.

*Full credit is given for two sentences containing the three words.*

Mental Age 12 Years.

46. "Which is the longer of these two lines?" Figure 12.
"Which is the longer of these two lines?" Figure 13.
"Which is the longer of these two lines?" Figure 14.
"And of these?" Figure 15.
"And of these?" Figure 16.

*Full credit given if suggestion of longer line to the right does not hold in last three pairs. One-half credit if it only partially holds.*

47. Test 45. *Credit given for one sentence containing the three words.*

Fig. 14.

48. "I want you to say just as many words as you can in three minutes. Some boys say as many as two hundred. Now you must try and see how many you can think of."

*Sixty words the minimum accepted.*

49. "What does charity mean?" "What does justice mean?" "What does kindness mean?" *Two correct answers required.*

50. "Find the sentences which these words make. Fix the words in their proper order."

(a) At-country-we-for-started-hour-an-the-early.

(b) Teacher-I-to-my-exercise-asked-my-correct.
(c) Defends-a-his-dog-master-good-bravely.

Mental Age 15 Years.

51. "I am going to say seven numbers. Listen well and repeat them exactly. 4-9-2-6-5-3-7; 9-3-5-1-8-2-6; 2-7-4-9-3-8-5." *One success in three required.*

Fig. 15.

52. "Do you know what the word rhyme means? Two words that rhyme are two words which end in the same sound. Thus *Pumpkin* rhymes with *napkin*. Pump-*kin*, Nap-*kin*. They both end in *kin*. The same way *Mutton* rhymes with *Button*. Mut-*ton* and But-*ton*. They both end in *ton*. Do you understand? Now I am going to give you a word and you try to find the words which rhyme with it. The word is *obey*. Find all the words that rhyme with obey."

*Three words required in one minute.*

53. "Listen carefully and repeat exactly what I say. The other day I saw on the street, a pretty yellow dog. Little Morris has soiled his nice new apron."

54. Tests Nos. 9 and 27. Interpretations required.

55. (a) "A woman was walking through a park in Chicago. Suddenly she stopped, dreadfully frightened. She ran to the nearest policeman and told him she had seen hanging to the limb of a tree a"—after a pause—"A what?"

(b) "My neighbor has just received some singular visits; one after another—a doctor, a lawyer, and a priest called. What is happening at my neighbor's?"

*Full credit given only if both problems are answered satisfactorily.*

Adult.

56. "Here is a paper folded in four, suppose that here (pointing to a small triangle which has been drawn in the middle of that edge which consists of but a single fold), I cut out this little triangle of paper. Now if I unfold the paper how would it look? Draw the paper as it would appear if unfolded and show how and where it would be cut." (Figure 10.)

*Requirements: Two diamonds drawn in line with each other and each in the center of one-half of a square.*

57. An oblong card cut in two along a diagonal is placed

Fig. 16.

in position before the subject. "Look well at the lower piece of card. Suppose that I lift it and place this edge (tracing the edge a-c with the finger) on this edge (a-b of the upper piece). Suppose further that this point (c) is placed just on this point (b). Now I take away the piece, in your imagination, place it as I have described and draw its outline in this position. Commence by following the outline of the first piece." (Figure 11.)

*It is required that a right angle be represented at (b) and that the edge a-c be shorter than the edge a-b.*

58. "What is the difference between laziness and idleness?" "What is the difference between event and advent?" "What is the difference between evolution and revolution?" *Two correct responses required.*

59. "There are three principal differences between a King and a President of a Republic. What are they?"

Required answer: Royalty is hereditary, the tenure of office is for life and its powers are very great; the President is elected, his tenure of office is limited, and his powers are less extensive.

60. "Listen attentively to what I am about to read. After finishing I shall ask you to repeat the sense of the selection: *Many opinions have been given on the value of life. Some call it good, others call it bad. It would be more just to say that it is mediocre, for on the one hand our happiness is never so great as we would have it, and on the other hand our misfortunes are never so great as others would have them. It is this mediocrity of life which makes it just, or rather which prevents it from being radically unjust.*"

*It is required that the thought of this selection be understood.*

53 West Fifty-third Street.

**Pulmonary Tuberculosis and Pregnancy.**—J. Colombet believes that the induction of abortion is not only justifiable in certain cases of pregnancy in tuberculous women, but is also beneficial to the patient. Abortion should be suggested and discussed as an elective procedure in these cases in the early months of gestation.—*Gazette des Hopitaux.*

## SOME EXPERIENCES WITH ANTI-TYPHOID INOCULATION.*

By JOHN W. BRANNAN, M.D.,

NEW YORK.

At the annual meeting of the Association of American Physicians at Atlantic City in May of this year, Dr. Leslie H. Spooner[1] of Boston related his three years' experience with antityphoid inoculation of the nurses in a number of hospitals in Massachusetts. Spooner was led to employ this prophylactic measure because a study of the records of these hospitals had shown a typhoid morbidity rate among the nurses very much in excess of that in the population at large. In the Massachusetts General Hospital it appeared that during the ten years previous to 1909, from two to six of the nurses had come down annually with typhoid fever. Inoculation was, therefore, offered to the members of the training schools and was promptly accepted. As a result the incidence of typhoid has practically ceased among the nurses of the hospitals which have adopted the procedure. The reactions following the inoculations varied in severity but were, as a rule, very slight or moderate in character.

After hearing Dr. Spooner's paper I returned to New York with the intention of having the nurses inoculated in the hospitals with which I am connected, Bellevue, Gouverneur, Harlem, and Fordham. I had not expected to make the inoculations myself, but there seemed at the time to be no one else to do it. I began the work in June, having been first inoculated myself by Dr. Norris, the director of pathological laboratories of the hospital. He used the vaccine of the United States Army, giving as the first dose ½ c.c., containing 500 million dead bacilli, followed at intervals of ten days with a second and a third dose of 1 c.c each. After each inoculation the arm at the point of injection was somewhat painful, tender, and swollen for 36 to 48 hours, the tenderness and swelling extending up and down the arm for a few inches. The general reaction consisted of a fairly severe headache, pain in the back, and some malaise, these symptoms lasting for about 24 or 36 hours. After I had received the second inoculation I proceeded to treat the nurses, using vaccine furnished by the Board of Health, of the same strength as that of the army, and in the course of the summer I inoculated some 200 nurses in the hospitals, and also about 50 members of the house staffs, as well as a few private patients, the latter being all men. The inoculations were all given on the outer surface of the left upper arm at the insertion of the deltoid muscle. The skin was sterilized with the tincture of iodine and the injections were made subcutaneously, not into the muscle. There were very few severe reactions, these being more marked among the men than among the women. Not more than three nurses asked to be relieved from duty for a day, whereas several of the internes were laid up for as much as two days at a time with temperatures ranging as high as 102°, with rapid pulse, nausea, vomiting, severe headache, and pain in the back. One of the doctors had a temperature of 103°, following each of two doses, both of them only ½ c.c. He had also what he described as a "splitting" headache, lasting for 36 hours, accom-

*Read at a meeting of the Practitioners' Society, November 1, 1912.

panied with great prostration and pain in the abdomen. Since the second inoculation (he has not wished to take a third) he declares himself as feeling better than ever before in his life. There had been very little typhoid among the nurses in Bellevue or any of the other hospitals, so that there seemed to be no particular reason for giving the prophylactic inoculation, but I urged that it be done, not only to protect the nurses while on duty in the hospital, but as a general measure of precaution, especially as many of them were about to take their vacations in the country, where they would be exposed to infection from sources beyond their control. No compulsion was exercised, but the nurses were advised that it would be to their advantage to undergo the inoculation. The great majority of the pupil nurses responded quite willingly, but a number of the graduates, who come for short periods of post-graduate instruction and experience, begged to be excused.

As I had heard of the occasional lighting up of latent diseases, such as arthritis, I inquired particularly as to whether anything of the kind occurred in these cases, but so far as I could learn nothing of the sort happened. It may also be of interest to know that the reaction was the same in the cases that had had typhoid as among those who gave no history of the disease. When some of the nurses and some of the doctors suggested that, as they had had typhoid fever, perhaps it was not necessary for them to be inoculated, I replied that not only did that not imply that they could not have the disease again, but also that from a scientific standpoint it would be interesting for them to receive the inoculation as "controls." They were not particularly impressed with my suggestion, which did not seem to appeal to their scientific spirit, but they accepted the treatment just the same.

It is unfortunate that we must use the word "vaccine," as it gives rise to apprehension as well as misapprehension among the nurses. It calls to mind their experience with vaccination against smallpox, and they are much relieved when they learn that the operation consists of a simple hypodermic injection and that the amount of fluid injected is small. In the army, Russell[2] employs the term "typhoid prophylactic," which has at least the advantage of not giving a wrong impression of the procedure itself.

Many of the nurses while undergoing inoculation were in close attendance on cases of typhoid fever in the wards, and Wright's "negative phase" more than once passed through my mind and the fear that I might be exciting an increased susceptibility to the disease. Nothing happened, however, and the nurses are now protected. It is to be hoped, as claimed by Richardson[3] and Spooner, that the danger of the negative phase of immunity said to follow bacterial inoculation has no substantial basis in fact, otherwise we might hesitate to make use of the procedure at a time when it would be of the most service, that is, in the presence of a local epidemic of the disease.

Some of the private patients who came to me for inoculation did so because they were about to go abroad, and feared that they might be infected by food or drink in the course of their travels. This argument is rather amusing when we consider that typhoid fever is much more prevalent with us than it is in European countries. A recent paper by Dr. Allen C. McLaughlin[4] of the United States Public Health and Marine Hospital Service shows that in 1910 in some 25 European cities there were 6.5 deaths in 100,000 population, whereas in this country in an equal number of cities of the same character there were 25 deaths in the same number of population. In other words, there is four times as much typhoid fever in the cities of the United States as in those of Europe, and as we know there is more typhoid in the smaller towns and in the country districts than in the large cities, it would seem to be much more reasonable for those who are about to spend their vacations in the country regions in the United States to be protected by inoculation than for those who are going abroad.

Many persons have wished to know the duration of immunity after inoculation, and I have usually replied "two or three years." Colonel Firth of the British Army, quoted by Major Russell,[5] concludes from his experience in India that immunity begins to diminish in about two and one-half years. In our own army, according to Russell, it is the present practice to revaccinate against both smallpox and typhoid at the beginning of each three-year period of enlistment. Martha Wollstein,[6] in a recent study on "The Duration of Immune Bodies in the Blood after Antityphoid Inoculation," found that these bodies reached their height within two months after the first inoculation and then fell rapidly within the next two months. Of nineteen cases under observation, the blood of fifteen was negative after thirteen months. Although, as Dr. Wollstein states, experience has proved that clinical immunity cannot be determined absolutely by the measure of immune bodies in the blood, she nevertheless believes that reinoculation with typhoid vaccine within a year is indicated when exposure to typhoid fever seems imminent. Russell, while noting the disappearance of agglutinins in little more than a year, adds, however, that they "are present as long after inoculation as after typhoid fever, which gives, as a rule, protection for life."

I should like to know if any one present has had any experience with the employment of sensitized bacilli instead of dead bacilli. In a recent number of the *New York Medical Journal*[7] reference is made to the method of Vesredka, in which 500 to 750 million sensitized living bacilli are given as a first dose, to be followed by a second dose of double the quantity some seven to nine days later. It is stated that there is no general reaction and only an insignificant local reaction following each injection. The paper to which the *Medical Journal* refers is by Alcock,[8] and is published in the *Lancet* of August 24. It is also stated that all authors agree that the vaccination by living microorganisms is more effective than when the dead organisms are used. If this be true, and the reaction is less severe, it would seem to be well for us to make use of this newer method, provided it can be proved to be free from the danger of conveying typhoid fever.

Since the above paper was read the records of the Bellevue Training School for the last twenty years have been carefully gone over by Dr. Robert J. Carlisle, the attending physician to the school, and Miss Brink, the superintendent in immediate charge of the school, and they were agreeably surprised to find that during this long period there had been but eleven cases of typhoid fever among the nurses in the hospital. It would be difficult,

perhaps impossible, to ascertain the number of nurses serving in the hospital during all these years, but it is undoubtedly very large. In addition to 525 nurses who completed their course of training, there must be counted the probationers who failed to qualify as pupils in the Bellevue school, and the hundreds of affiliating nurses and graduates of other hospitals who come to Bellevue for post-graduate instruction and experience.

Another note of interest must be added. Early in November a pupil nurse—now happily convalescent—contracted typhoid fever in the hospital. She was one of seven who had refused inoculation. On the other hand, of eighty-three who accepted the typhoid prophylactic not one has acquired the disease, though they were all more or less exposed to infection throughout the summer and early autumn. The occurrence of this case has not unnaturally had a marked effect in influencing the other nurses to undergo inoculation.

## CONSERVATIVE TREATMENT OF TUBERCULOUS GLANDS OF THE NECK, BASED UPON THEIR PATHOLOGY.

By JAMES SPENCER BROWN, M.D.,

MONTCLAIR, N. J.

SURGEON IN CHIEF, MOUNTAINSIDE HOSPITAL.

Few diseases demonstrate so strikingly as scrofula the interaction of infecting and infected organism. And in this disease the clinical pictures varies to a remarkable degree. Hospital and dispensary miss the more frequent (the earlier) manifestations of glandular tuberculosis; while on the other hand the attention of a practising physician is but little directed toward the more extensive involvements since his patient consults a surgeon for more radical treatment. The point of contact changes remarkably one's attitude to scrofula, and statistics differ greatly as to frequency, intensity, and mortality.

For the past four years the writer has been treating tuberculous cervical adenitis in accord with a better understanding of living pathology, and applying this knowledge along the lines of physiological surgery rather than what are termed radical methods. The success attained from these more conservative methods points to a sound basis in pathology.

As is well known, epithelial surfaces ward off many attacking microorganisms; but it is the mesoblastic tissues which must bear the brunt of protection. The omnipresent polymorph may be able of itself to conquer the invaders, or at least to hold them in check until the body as a whole can muster sufficient chemical forces to annihilate the enemy; or the slow-moving connective tissue cells can imprison and starve the invaders to death. With the tubercle bacillus other tactics are necessary: the light-armed polymorph can only lay down its life in delaying the advance; mononuclears, large and small, are better equipped; but on the stroma cells depends the outcome. Moreover, the tubercle bacillus may remain hidden when odds are against it, and it is capable of withstanding a very prolonged siege in a state approaching hibernation.

In low metazoans, tissue-juice exchange is carried on directly in the common sap-bed supporting the cells. In higher organisms the economy of specialization necessitates a more rapid and definite transfer of food and waste materials. Of body outposts, none is so important as its chains of lymph glands along the main avenues of approach. The streams must pass through these glands, which remove more or less thoroughly harmful materials, chemical and physical.

Studies of various investigators, notably Flemming, Sabin, and Kling, seem to demonstrate that the first indication of a lymph gland is the formation from a preexisting lymphatic vessel of a labyrinth within which an artery breaks up to a capillary rete, and about the rete lymphocytes appear, probably by proliferation of stroma cells. Neighboring branches of the artery develop retes and about them also appear lymphoid clumps ("follicles"), several of which are usually grouped together within a single capsule to form a "gland" or "node."

It is at the hilum that the blood-vessels enter the gland, arteries passing almost immediately to the lymphoid tissue (follicles and their prolongations, the "cords") in which they form retes, then reuniting pass out into the trabeculæ as veins. Thus both lymphatic and hemic vessels emerge at points different from the entrant vessels. The course indicates that the follicle is in special relation with the hemic system rather than the lymphatic, and this is borne out by embryological and pathological observations. It is thus seen that the gland may be injured through both lymphatic and hemic channels; in the one case the sinus-system being first endangered and in the other the follicle-system. The gland is entirely mesoblastic, composed as it is of lymphocytes, endothelial cells, and more stable connective tissue. Afferent ducts come from the periphery or from higher glands; efferent ducts empty into lower glands and eventually into the hemic system near the junction of the internal jugular vein with the subclavian.

The glands interesting us at present are interpolated in lymphatic chains which girdle the neck at its junction with the head and pass down from this collar in the parotid region beneath the sternomastoid and under the clavicle to the thorax, where, after anastomosing with axillary and mediastinal lymphatics, they empty into the great ducts, and thence enter the hemic circulation. The glands are grouped in three regions: (1) submaxillary, where discharge the lymphatics draining buccal cavities and gums; (2) the region immediately behind and below the angle of the jaw, draining tonsils and nasal and pharyngeal mucous surfaces; (3) beneath the sternomastoid, which drain, either as primary or secondary glands, the entire head and neck.

Entrance of the tubercle bacillus to the lymphatic system through apparently normal skin must be very infrequent, though its possibility has been demonstrated by Courment and Lesieur; and glandular

involvement secondary to lupus is likewise rare. In most cases entrance is gained through the alimentary or respiratory tracts, whose portals are drained by these cervical lymphatics. The surfaces of nasal and oral passages, though well protected by mucus, cilia, muscular movements, etc., present better opportunities for penetration than cutaneous surfaces, since local distention is facilitated by moisture, the covering is thinner and softer, the subepithelial tissue looser and juicier, and drainage more efficient. Further, trauma is naturally a very common occurrence, and through crevices which we can scarcely detect microscopically, much less grossly, the bacillus may enter. Since the first noticeable glandular enlargement is usually beneath the posterior belly of the digastric as it crosses the sternomastoid, and since this gland drains the tonsil many observers regard the tonsil as the commonest portal of entry. There can be no doubt, however, that the other lymphoid tissues forming the end of the visceral lymph-nodular system (Waldeyer's ring) are very important, and nasopharyngeal growths, catarrh, irritation of lymphatics are frequent preludes to tuberculous infection. Whatever tubercle bacilli may be in food or drink or air must pass this tonsillar ring.

Infection does not depend merely, or even to any great extent, upon the presence of a bacillus on, or beneath, the surface, since we all doubtless receive and destroy or discharge many tubercle bacilli daily; and many times the bacillus produces a localized lesion without our being aware of it. A child, even though healthy, readily acquires an infection; but if the child be of an atonic family, be of "lymphatic" frame (that is, with mutable and poorly matured mesoblastic tissues), be aprosexic, with adenoids and large tonsils, and, furthermore, live an unhygienic life, eat unhygienic food, and, most important, associate with an unhygienic person already tuberculous, the disease is readily acquired.

Race, climate, and other factors contribute to the liability to infection; but hygiene is the solution of nearly all.

When the disease appears in an adult the infection is usually through the air (dust and droplet infection); in children, however, the alimentary tract plays an important part, since the bacilli penetrate the epithelial barrier, enter lymphatics, pass through glands to the thoracic duct and thence to the blood. All stages of this cycle have been traced a result of the work of many investigators, such as Cornil, Calmette, Rosenberger, Vansteenberghe, and others. Living tubercle bacilli in the cervical lymph glands of persons with no gross lesions of the disease are not nearly so frequent as in the mesenteric glands.

Pathological studies demonstrate, as we should expect on anatomical grounds, that there may also be infection of the glands through the blood-stream aside from miliary septicemia. In a chart of clinical and pathological data, an attempt was made to differentiate by histological picture the hematogenous and lymphogenous infections. While in practically every case of scrofula lesions were found in the marginal sinus, and at the periphery of the follicle (probably in the sinus wall), occasionally others lay in the heart of the follicle or but slightly excentric; and a section would sometimes show both pictures. Whether this can be taken as evidence of a hematogenous origin or not, we do know that in practically every case of pulmonary tuberculosis the bacilli are to be found in the blood. The percentage is smaller in scrofula.

Even in the simplest case we find that the glands may differ markedly in size and appearance, and the lesion varies with the type, virulence, and number of organisms, with portal of entry, and local and general somatic reaction.

When the bacillus has localized in a gland or elsewhere, it multiplies rapidly and throws out its products of metabolism as protective agents. The body as a whole is first apprised of the invasion by these products (toxins) and later by symptoms of localization. Local polymorphs, after their fashion, seek to ingulf the germ, other polymorphs are hurried to the scene, together with wandering cells of various types, and surround it. Local fixed cells proliferating, contribute to the walling in. Then ensues destruction of body cells and germs, and in the body's efforts to clear its field, the accumulating débris takes the path of least resistance to a surface upon which it is discharged.

Now, young tissue has a better chance to grow in and may terminate the conflict in scar formation. This, in general, is the chain of events, whatever the class of invading organism; but details vary for each class and are fairly characteristic wherever localized. The toxins of the tubercle bacillus are less acutely poisonous than those of many germs, hence the barrier is better developed, forming a nodule or tubercle. Though occasionally a few epithelial cells may be included and though the toxin undoubtedly produces an epithelial proliferation, the tubercle is for the most part of mesoblastic origin, its constituent cells derived from the blood as lymphocytes, or from the endothelial and stroma cells. All these may become epithelioid cells, and according to the circumstances pass through the various polyblastic stages to the formation of a connective tissue scar. Certain authors even state that the giant cells may break up to fibroplasts and produce connective tissue. Keeping this in mind we may reckon with tolerable accuracy the virulence of infection and resistance. Theobald Smith considers a tubercle as the resultant in the struggle of bacillus and host through past eons, and that its tendency is to the conservation of both bacillus and host. Certainly tissue selection is almost specific.

The tubercle bacillus can also produce a more diffuse granulation, seen especially in lymphatic children invaded by a large number of virulent bacilli, and the granulations may be so numerous and so vascular and so low in the polyblastic cycle as to seem structureless. Epithelioid cells and shrunken giant cells are scattered about and a coagulation necrosis may ensue, not unlike that of Hodgkin's disease, lymphosarcoma, or leukemia. Later, definite nodules may develop.

From the foregoing statements concerning glandular tuberculosis in general, and from the pathological findings seen in the laboratory, one fact presents itself of paramount importance for the treatment of this disease, namely, that these patients are suffering not with a local disease, but with a general systemic infection which at this time is held in check by a good resistance.

We first observed this several years ago while doing the block dissection. At that time we were removing in all cases the glands and gland-bearing fascia, and yet we always found minute glands following along the vein, so deeply placed that complete removal was impossible. These small pin-

head glands were thought to be merely toxic, but on section many were found to be tuberculous. However, in these cases healing occurred by primary union and the patients are alive and well today.

It was customary at that time to treat all small single glands, whether with or without sister glands, first, by removal of the portals of infection (tonsils, adenoids, etc.), and secondly, by simple incision into the suppurating foci. This latter procedure led into many difficulties, since a second infection was often added.

If one of these simple cases is treated by a radical operation we find that the process which began as a bacillus and ended in caseation and pus-formation, is being well taken care of by the host at the time of operation. It may also readily be seen that incision into the abscess cavity would open new portals of entry and that the tissues in their fight to prevent further bodily involvement could not carry on the war so magnificently waged.

While experimenting upon these cases in search of a better method of treatment, the writer began to pay more attention to general therapy of the patient and to treat the abscess with more respect. It was quite evident that if we could imitate nature and increase local edema and cell-proliferation before operation and then evacuate the caseous masses without infecting with other organisms, nature would be quite capable of handling her enemy, the tubercle bacillus. After trying to accomplish this end in different ways I hit upon a procedure which seems entirely satisfactory, namely—the production of a Bier hyperemia by a simple elastic band about the neck for a few hours before opening the abscess. Thus we increase edema and cell-proliferation.

Then, a very small straight incision into the gland, evacuation of the contents by a dull spoon, using no force or rough manipulation, and being careful not to break through the capsule nor to invade the protective phagedenic zone; and without washing or wiping out the cavity, the introduction of 2 to 4 per cent. formalin in glycerin and sealing the incision.

Now what happens? This: primary healing in 50 per cent. of the cases. Of the remaining 50 per cent, 30 per cent. have only a serous discharge, which ceases after three or four more injections, and the remaining 20 per cent. suppurate, more or less, depending on the delicacy and completeness of technique.

At the same time this local treatment was started we began a more systematic attempt to increase the general resistance of the patient. Forced feedings, twenty-four hours a day out of doors, and other methods of treatment which were recognized as applicable and beneficial in all cases of tuberculosis. The treatment of these simple cases was so successful that we applied our methods to more extensive gland involvement.

At this point we introduced the injection of tuberculin B. This procedure, so far as we were able to tell, had little or no effect (sixteen cases). We should probably have given it a more extensive trial had we not been induced by Prof. J. E. Temple of Cornell to try the enzymes of yeast. This has seemed to be the connecting link needed in the treatment. Since that time we have applied it in more than eighty-five cases. Fifteen of these cases were treated until we became satisfied that some more radical method was indicated to start the process of body-repair.

Of the other seventy cases fifty-six are well without gland involvement; ten are recent cases under treatment; three were lost sight of after the first treatment, and an infant with both cervical lymph-chains involved died with some intercurrent summer diarrhea while away from home.

Though these cases are limited in number, we feel that we have had sufficient experience to recognize the type to which conservative treatment is applicable. In a general way it may be said that any superficial gland, or chain of glands, may be treated in this way, providing we can satisfy ourselves that the caseous masses are acting as foreign bodies. It must be remembered that not the tubercle, but the germ is harmful. Opening allows the escape of toxins, and of the caseous material which acts as a foreign body, preventing granulation and approximation of surfaces. This caseation is the result of the tubercle, due in part to coagulation necrosis from anemia, to toxins from the bacillus, and to an enzyme found by Opie and others in the epithelioid cells themselves.

In yet another class of cases treatment by incision, injection, and exhibition of enzymes is markedly efficacious; namely, the rapidly developing abscess of the adult, sequent upon a glandular tuberculosis. This condition is not infrequently bilateral, and the abscess has the characteristic tuberculous tendency to burrow, often extending along fascia planes to the chest, or penetrating between muscles of the shoulder girdle. Under the treatment indicated, the abscess heals rapidly with minimum of suppuration, though its cavity may have contained a quart or more of cold pus.

Sometimes, even though the small incision is omitted, the caseous matter may disintegrate, may be invaded by granulation tissue, and healing by hyaline scar may ensue; or it may be surrounded by fibrous tissue and compressed to a tiny spot; or its fatty acids and soaps may combine with calcium salts, becoming firmer and more friable, and eventually be definitely calcified. All these processes of self-cure are common.

Large, multiple, deeply-seated glands are not to be dealt with by conservative methods. A more radical procedure is necessary, since these glands are all caseous with a conglomerate of tubercle producing many foci of dissemination often matted together, and, as can readily be seen by open dissection, lie one above the other, the lowest not being felt until the others are removed. An exaggeration of this type is often mistaken for Hodgkin's disease, since the glands are so large and numerous as to form a collar about the neck.

"Radical operation" for cervical glands is a misnomer. No operation for this disease can be radical, since the glands are so numerous that complete removal is impossible. The most we can do is to remove the lymphatic chain involved, with its infected outlying glands and the gland-bearing fascia. Such an operation presupposes a proper knowledge of anatomy; does not mean a limited incision, but open work—exposure of the vein and avoidance of the motor nerves. Any half-hearted dissection, without removal of the gland-bearing fascia, is meddlesome surgery; and if the result of such an operation is satisfactory it is sufficient evidence that the case was one deserving more conservative methods of treatment.

For nearly three years frequent attempts have been made by the writer to investigate in lower animals the action of the yeast enzyme. The small animals—mice, guinea pigs, and rabbits—do not bear the enzymes well. However, we have accomplished something. But because of the lack of accurate scientific data we are not ready to report upon this part of our work.

Our experience, then, would lead us to these conclusions:

(1) Scrofula is a tuberculosis of the patient, not merely of the glands; hence, prophylactic and therapeutic hygiene as well as local treatment is indicated.

(2) Complete extirpation of the disease is impossible, and if given opportunity, Nature tends to cure; hence, judgment as to treatment is necessary.

(3) The glands have an important protective function; hence, the surgeon should employ no more radical method than he must, and the glands should not be carelessly sacrificed.

(4) In a great majority of the cases the removal of the caseous masses by a proper technique is all the local surgery needed.

(5) The enzymes of yeast seem to be of benefit.

## RECENT FRENCH PROGRESS IN MEDICAL RENAL DISORDERS.

By CECIL KENT AUSTIN, M.D.,

PARIS, FRANCE.

The lay scoffer is still very much to the front with his time-worn taunts against the medical man, whom he looks on as an individual sleepily gyrating in a never varying circle, his shoulders burdened down with tradition, prejudice, and etiquette. "Look at the surgeons," he cries; "see the wonderful things that they are accomplishing. Why cannot you physicians accelerate the pace a little bit?"

We of the medical side are still, unquestionably, struggling with difficulty against our multitude of determined pathological adversaries, no such extraordinary and colossal streak of luck having as yet fallen to our lot as to the gentlemen of the knife, whom a clear-seeing chemist (and *not* a surgeon) freed forever from the nightmare of infection, with a single discovery clearing the field for all their future audacities. But still, however much our present status may leave to be desired, when compared with the complacency and liberty of action of the surgeon, the immense effort that is being put forth by the medical profession in the different countries is slowly but surely bringing their province also gradually out of darkness into light, and reducing into some semblance of order what has until recently been a state of affairs not altogether dissimilar to primeval chaos.

The special field of which I wish to speak today—medical nephritis—has been one of the latest to be taken in hand. But the work that has been accomplished in this branch during the past ten years, and in particular by a set of young French scientists in Paris, has at last brought it also into line and introduced into it a certain degree of general order, whereas previously a bewildering state of incoherence was the best that was at our disposal. The researches of Widal, Castaigne, Achard, Javal, Albarran, Ambard, and others have, as a matter of fact, effected for nephritis very much the same fundamental clearing work as was carried out by Charcot when he first took hold of diseases of the nervous system fifty years ago. For I think that it is no exaggeration to say that if a physician who graduated only fifteen years back, and who, let us say, for one reason or another had paid no attention whatever to kidney diseases since that time, were to-day to pick up the most recent French monograph on nephritis, he would find himself in an entirely new atmosphere of which he hardly understood even the terminology. He would, in fact, be obliged to begin by forgetting all that he had ever learned on the subject, and take it up entirely anew.

For what did the man of only fifteen years ago know about nephritis? He was taught that there were acute and chronic forms, and parenchymatous and interstitial varieties; he studied under a microscope the big white kidney and the small retracted one; he tested the urine for albumin, and, if he was an advanced laboratory man, he experimented with urinary toxicity. Then when that had been done he told his patient to go on a milk diet for the rest of his days—full stop—and that was all. If, as not infrequently happened, his client had a rooted aversion to milk in any form, the medical adviser had practically no alternative to offer, and the patient got along as best he could on any haphazard régime.

That was all only a short time ago, the first step in advance having been made by Widal at the beginning of the century. These researches and experiments of Widal's concerning the action of faulty elimination of chlorides in producing edema in certain forms of nephritis were followed by similar demonstrations as to nitrogen retention in the blood. Various means were devised for testing clinically the value of the kidney as a filtering organ. An entirely new classification of nephritis was advanced and accepted by everyone. The old state known as uremia was given another name and divided into altogether new forms. And, lastly and principally, the whole question of treatment, after all the only one of importance, was completely revolutionized and put on an intelligent and reasonable basis, to the relief of the medical man, and to the incalculable benefit of the patient. Since all of this work is relatively new, and has appeared in French; and since there are reasons for believing that even in its land of origin it has not yet found its way into the rank and file of practitioners, many of whom have not even grasped the significance of the simple chloride idea, but believe that *all* persons presenting medical albumin in the urine must be put on a chloride-free diet, it seems as though a brief review of the present situation may not be untimely. This I shall do in as general and elementary a fashion as possible, simply to call attention to the matter and awaken interest in it, referring the reader desirous of more complete information to any one of the many monographs that have appeared in France on the question of late, but above all to Castaigne's small handbook "Les Maladies des Reins," published only a short time ago.

In the conception of the young French school the old anatomical classification of nephritis is set aside as being of merely academic interest; their view of the question is a purely practical, clinical one. They treat the kidney as a common filter, which may or may not be carrying out its function properly. When it does so it is called permeable; when defective, more or less impermeable, such impermeability being at times elective, at others general. Defective action may be either plus or minus; that

is to say, the organ may either filter too freely, for instance, it may allow substances to escape that are usually retained in the blood, as is the case when albumin appears in the urine; or it may not filter sufficiently, damming up in the blood and its outlets substances that normally pass freely through the filtering organ, such as chlorides or urea. Such defective filtering, when minus, often reacts on the circulating system, heart and arteries, producing degenerative lesions, increased tension, cardiac hypertrophy, etc.

These few general ideas will render comprehensible the classification now introduced of medical nephritis, which is divided into four forms: albuminous, chloremic, uremic, and cardiovascular—the four being susceptible of a variety of combinations. It should here be stated with particular emphasis that in the present order of things uremia refers to an altogether new conception, the retention of urea in the blood, and not to the old idea of the general terminal state of nephritis preceding death; this is now known as renal insufficiency. This point cannot be too carefully borne in mind.

The conception of the kidney as a more or less permeable filtering organ has led to the creation of an entirely new chapter in the question, the study of the means to be employed for ascertaining clinically the degree of permeability of a patient's kidneys. And I cannot give a better idea of the amount and importance of the work that has recently been put in in this department than to point out that Albarran's book on the means for testing renal permeability is a work of five hundred pages. Fortunately, however, it is not necessary for the practitioner to go into the subject quite to that extent, and at the present time it will be amply sufficient for him to use, when circumstances seem to indicate it, the methylene blue test, which is extremely simple and well within the attainments of the most ordinary practitioner. A hypodermic injection of one cubic centimeter of a solution of methylene blue is made, under certain specified conditions, and then the urine is taken at frequent intervals and its color noted. This blue passes very quickly into the urine, whose coloration, under normal conditions, rises steadily to a certain intensity in a given time, remains there a while, and then decreases to extinction, also in a fixed period. The whole affair can be indicated by a graphic curve, resembling somewhat the chart of a pneumonia patient; its laws are now well known, and it is the greater or less deviation from the normal type that reveals the degree of impermeability of the kidneys.

Attention having been called to the kidneys by certain symptoms, possibly by the discovery of albumin on routine examination, as for life insurance, the problem for the physician is the following: to test the efficiency of the renal filter, and, in case of deficiency, to ascertain whether there is chloride or urea retention; also to explore the condition of the cardiovascular system, degeneracy, high tension, hypertrophy, galloping rhythm, etc.

A patient with albumin in his urine may be otherwise in an absolutely satisfactory condition, and remain so for years and years. His filtration may be perfect to the methylene blue, his tension and heart normal, and there may be neither chloride nor urea retention. Such a patient can therefore be allowed wide liberty in diet; he merely requires careful watching and retesting at regular intervals, but on the whole his lot is by no means an unhappy one. In former times he would, of course, have been consigned to a milk diet, *nolens volens*. This is practically an entirely new type of nephritis in medicine, one that is by no means rare, and a class of patients which has derived infinte benefit from the advance in the study of nephritis.

Another patient, with more or less edema, will be found to show a large amount of albumin in the urine, and there may be headache, dyspnea, nervous symptoms, or convulsive attacks. The test with methylene blue is normal or even plus; cadiovascular signs are absent; the amount of urea in the blood does not exceed the normal maximum of half a gram per liter; but the patient is found to be in a condition of chloride retention, the power of filtering this substance being for the time arrrested in the kidneys to a greater or lesser degree. This chloremic type is a common form of acute nephritis, and is most interesting as a subject of study, on account of the facility and accuracy with which an excess of chlorides in the system can be demonstrated to be the edema-producing factor. For reasons still unknown, as soon as the percentage of sodium chloride in the blood exceeds the normal figure, Nature gets rid of it at once by pouring it out of the circulation into the interstitial and cellular tissues, or into the virtual cavities of the body. Once there, however, the sodium chloride can be tolerated by the tissues only at a given point of dilution; it therefore attracts to itself the necessary amount of serum for this dilution, and it is this process that gives rise to the various forms of edema, anasarca, effusions into the peritoneal, pericardiac, or pleuritic cavities, or to the more insidious conditions of interstitial infiltration of the viscera—brain, lungs, or digestive tract. These deeper forms can exist quite separately from the superficial, visible forms, and are the basis of most of the clinical visceral symptoms of this condition—headache, disordered sight, vomiting, dyspnea, etc., as can be so readily demonstrated by a chloride-reduction diet or lumbar puncture. Of the two forms of nephritic retention, the chlorides and the urea group of substances, this is by far the least serious and most amenable to treatment. Nothing can be more gratifying to the practitioner than the way in which a typical case of this category reacts to intelligent management. Such a patient, with proper handling, will in a few days' time pass from a waterlogged condition with headache, dyspnea, and vomiting, to one of comparative comfort in which he can confidently await a gradual return to relative health. This class of cases also has benefited enormously from the new ideas as to the diet suitable to such conditions. The old milk diet was, to be sure, already one in which the chlorides are reduced to a very low figure, about 1½ grams per liter; but its weak point was that to a system already burdened with an excess of liquids it brought a still further excess, so that the end, though attained, was attained much more slowly than by the present method. It had been found empirically to fill the bill, but it did so only in a lame and half-hearted manner. Nowadays this type of patient receives an almost luxurious diet; plenty to eat, but only articles containing a minimum of NaCl, such as meat, fresh-water fish, eggs, dried leguminous vegetables, cereals, herbaceous vegetables, fruit, milk and fresh cheese, and a variety of minor substances for seasoning. The preparation of many of these dishes without salt does not render them particularly palatable, and it is not long before the average patient commences to cry out for his usual seasoning in a more or less determined fashion. But to begin with, when dealing with one of the

many people who have a horror of a milk diet, the physician is only too thankful to have at his disposal this precious alternative; and in the next place, it is generally possible by this means to gain the necessary few weeks for tiding over the crisis, at the end of which period it is admissible to allow the patient a weighed amount of 2 to 3 grams of NaCl per diem, which he can distribute over his food as best he sees fit, without any very great detriment to his progress.

The next form we have to deal with is perhaps the most interesting, on account both of its relative newness and of its great clinical importance, since in a way it commands the entire *prognosis* in chronic nephritis. In the case of the albuminous form, the chloremic variety, and the cardiovascular type yet to be considered, the patient's outlook, at least for the immediate future, is as a rule fairly good. Under proper management, and granting the necessary docility in submitting to diets often not particularly appetizing, the patient's survival is frequently a very protracted one, although the remote prognosis is always serious. But with the appearance of urea retention opens the period of storms; so that with any case of renal impermeability the all-important point is: Is there or is there not urea retention; if so, what is its percentage, the prognosis being based on that detail in a manner that can almost be called mathematical?

Differing in this respect from chloride retention, urea and its minor relatives, when prevented from passing through the renal filter in a normal fashion, do not flow out of the circulation into the surrounding tissues, but remain in the blood or in the normal or pathological humors of the body, and experience has shown that their percentage is alike in all of them, whether blood serum, spinal fluid, or effusion into a normal cavity (pleurisy, ascites, etc.) Now the amount of urea in these liquids has to be measured by the customary chemical processes. When there is no effusion present, and when spinal puncture is not indicated by some predominating symptom, we are obliged to fall back on blood serum, of which about 10 cubic centimeters are required for an analysis. This can either be obtained by wet cupping or by the insertion of a needle into a vein. When lumbar puncture has to be done the opportunity should never be omitted of making the necessary dosage; but the ideal situation (for the experimenter) is that in which there is effusion into one of the natural cavities; in such a case the practitioner has constantly the material at his disposal for all the tests he may desire.

Now experience has shown that the extreme normal limits for the urea percentage in these liquids extends from 0.15 to 0.5 centigrams per liter of serosity. In the zone extending from 0.5 to 1.0 gm. come the moderate cases of urea retention, those in which the danger is not immediate. But from one to two grams denotes a serious condition, in which the patient generally does not last more than a year; while above two, through three, and up to four, the survival is a question merely of a few weeks or at most months. The estimation of this percentage is a little beyond the capacity of the average medical man, but well within that of any chemist, and nothing is easier than to take the required amount of serum from a patient and mail it to a laboratory in the nearest town, where the test can be made in a few hours.

This category of patients also has profited greatly by the changed ideas as to the diet best suited to such forms of nephritis. Since the pure types of this variety are quite "dry," that is, show no edema whatever, the question of liquids is with them one of minor importance; what they chiefly require is a diet in which nitrogen is either very much reduced or eliminated entirely. This is possibly an easier régime to establish, and to get the patients to accept, than the chloride-reduction diet. It consists in prescribing nothing but sugars and starches. Of these there is a wide scale, and a moment's reflection will show any medical man that it is far easier for a patient to eat a lot of grapes, a baked potato with butter, or rice with sugar and cinnamon, than it is meat, lentils, or bread without any salt.

The fourth, or cardiovascular type, is such a familiar one that there is nothing particularly new about it to render it of special interest for the moment; so we will pass immediately on to the consideration of renal insufficiency (formerly called uremia).

This condition in reality scarcely deserves special description, since it is naturally not a morbid entity by itself. There is always renal insufficiency, from the moment that either of the two main forms of retention sets in, uremic or chloremic; it is only a question of degree. The old term uremia merely denotes the stage at which these conditions enter the danger zone. There are, then, these two varieties of insufficiency, the prognosis of the one, the dropsical form, being infinitely less alarming than that of the other, the "dry" and more insidious variety. The main clinical symptoms of the latter are, in addition to a watery urine containing a relatively low percentage of albumin, first, a loss of desire for food, extending sometimes to positive repulsion; second, cerebral torpor; third, pruritus; fourth, retinitis.

Treatment of the dropsical forms (chloremia) having already been referred to, that of the uremic type must now be mentioned. As good a way as any to begin with is what is known as a Guelpa cure of two to five days; this consists in an absolute water diet, with or without lactose, and a brisk purgation each morning. If there is no chloremia accompanying the uremia, a glass or two of a natural purgative water will suffice; in the opposite case scammony, or calomel, or some similar non-salt preparation, will be more advisable. This can be followed for a few days by a grape cure, during which the patient is required to consume two to three kilos of ripe, sweet grapes per 24 hours. At the conclusion of this stage the glycoamylaceous diet should be gradually established, and the patient given to understand, in guarded language but clearly, if possible, that the situation is a serious one and the outlook for the immediate future grave; and the relatives should be warned, according to the uremic degree reported by the chemist, as to the probable duration of the patient's survival.

In the foregoing paragraphs an effort has been made, under perhaps not altogether ideal circumstances, the article having been written at sea away from works of reference, to give a bird's-eye view of the present state of this question in France. It is one with which every practitioner should lose no time in making himself familiar, as it has been rendered in the hands of its gifted promoters preeminently *practical* and *clinical*. Whether considered from the viewpoint of diagnosis, prognosis, or therapeutics, it is of the deepest interest and importance. Nephritis is a common everyday disorder. Up to a few years ago this question was in a

state of utter darkness, and the treatment of the condition blind empiricism. But at the present time, thanks to the unremitting efforts of perhaps two men—Widal and Castaigne—it has been put on a matter-of-fact, intelligible basis, and the service thereby rendered to this large class of patients cannot well be overestimated.

20, Rue Chalgrin.

## A FATAL CASE OF GONOCOCCUS SEPTICEMIA.

By G. A. RUECK, M.D.,

NEW YORK.

The reason for reporting this case is its great clinical similarity, at least during the first 26 days of the disease, to typhoid fever and the small number of cases of gonorrheal septicemia on record.*

Mrs. A. S., German, 22 years old, married, was in St. Francis Hospital, New York, from August 21 to October 26, 1911. The family history was negative.

*Previous History.*—She had measles when a child and acute articular rheumatism with "valvular heart disease" at the age of 12. Two years ago she suffered from an attack of acute purulent otitis media of the right side. This condition became chronic. For the last four years she had palpitation of the heart and dyspnea on slight exertion. Her feet would swell up toward night. The menstruation was normal. She was married four weeks ago, one week before the beginning of the present illness. Three weeks previous to her admission to the hospital she began to have continuous headaches and "an aching pain in the bones," especially in the knees. There was no epistaxis, no vomiting, no diarrhea, no cough, no expectoration, no hemoptysis, no nightsweats, no drowsiness, and no pain on urination. Nycturia occurred only once. The bowels were regular. The appetite was poor and the sleep restless. She was in bed for two weeks before admission to the hospital.

On admission her chief complaint was of headache, general fatigue and aching in the body, difficulty in hearing, and great thirst.

*Physical Examination.*—Temperature 104°. Pulse 120, regular, of low tension and small volume. Respiration 32. Patient was slim, of middle size, and anemic. The facies had a typhoid look (pale, dull, apathetic). The pupils reacted to light and accommodation; conjunctiva and iris were not inflamed. There was a discharge from the right ear; a bacteriological examination of the pus was not made. The left ear was normal. Tongue was coated, tip red. The lungs were normal.

Heart.—Slight systolic murmur in mitral area and at apex, transmitted to axilla. Towards the end of the disease the murmur increased in intensity and became loud and blowing.

Abdomen.—No rose spots, no tenderness, no tympanites, no gurgling sounds. During and after the fourth week of the disease a few small petechial subcutaneous hemorrhages, about 1 mm. in diameter, scattered over the abdomen, not disappearing on pressure, were noticed. At times there were only one or two, at other times six to eight present. The liver reached to the subcostal margin. The spleen was palpable but not tender.

Extremities.—The knee-joints were red, swollen and very painful for a period of 5 days during the fifth week of the disease. At other times joint-symptoms were slight or absent. Babinski and Oppenheimer reflexes were absent; the knee-jerks were normal.

Pelvic examinations by two visiting physicians and one visiting surgeon on three different occasions were negative.

Clinical Diagnosis.—Typhoid fever, mitral insufficiency, chronic purulent otitis media.

The patient was treated for typhoid fever while in the hospital. She received two rectal irrigations a day for the first four weeks, then one rectal irrigation a day. The legs and knees, when painful, were painted with guaiacol and wrapped in cotton.

Routine laboratory examinations were made by Dr. Hiram Gallagher, medical interne. Urine Analyses: August 23, 1911. Urine clear, blood-orange color, specific gravity 1025, acid, acidity 50 (in terms of decinormal sodium hydroxide), albumin +, sugar 0—microscopical=many casts, epithelium ++. Diazo-reaction was negative.

September 16, 1911. Urine very opalescent, dirty-brown color, marked brown-gray precipitate, specific gravity 1014, acid, acidity 20, albumin +, sugar 0; miscroscopical: pus +++ .

October 14, 1911. Urine very dark, bloody looking, marked grayish precipitate, specific gravity 1012, albumin ++, microscopical = red and white blood-cells +, casts ++++.

Blood.—On September 2 the white blood-cell count showed 8,000 leucocytes. On October 17, 8,000 white blood-cells were counted.

Five smears from cervical and vaginal secretions on different occasions showed absence of Gram negative diplococci.

Examination of the feces on October 18 showed many red and white blood-cells, amorphous débris, bacteria, and starch granules. The sister in charge of the case described the stools as follows: "In the beginning they were like those in typhoid fever. During the last three weeks of the disease they were pussy, blood-stained, and of a foul, unbearable odor."

Examinations of the blood-serum by myself: August 24, 1911. Macroscopical Widal reaction for *B. typhosus* with dilutions of the patient's serum of 1:40, 80, 160, 320=negative.

October 3, 1911. Macroscopical agglutination-test with dilutions of the patient's serum of 1:40, 80, 160, 320 for *B. typhosus* and *B. parathyphosus* =negative.

October 13, 1911. Macroscopical Widal reaction for *B. typhosus* and *B. paratyphosus* negative.

October 14, 1911. Wassermann reaction negative.

The temperature-curve in the beginning of the disease was like that of typhoid fever, and the physicians in charge were convinced of the correctness of this diagnosis in spite of the negative laboratory report. On the 26th, 27th, and 29th days of the disease the patient had chills followed by profuse perspirations. Then the temperature-curve was like that of sepsis. Now pelvic examinations and microscopic examinations of the vaginal discharges referred to above were made on different occasions with negative results. On the 46th day of the dis-

*Only cases of gonorrheal septicemia where gonococci have been isolated from the blood and properly identified by their morphology, cultural character, agglutinative, etc., properties are here considered. Stained blood-smears alone are absolutely insufficient. Marcel Faure-Beaulieu in 1906 collected 34 cases of gonorrheal septicemia diagnosed by a bacterial examination of the blood. Dieulafoy in 1909 counted 37 cases, his own two cases included. Only one additional case, as far as I know, has since been reported by Weitz.

ease the temperature came down to normal and remained low to the 56th day, but the patient was very weak. On the 57th day of the disease the temperature rose again, ranging from 100° to 102° F. This was taken for a relapse of typhoid fever.

October 14, 1911. The patient was very weak, nervous, at times, delirious, and suffered from diarrhea. I made two blood-cultures squirting 5 c.c. of the patient's blood from the median basilic vein into each of two Erlenmeyer flasks containing 100 c.c. of glucose (1 per cent.), calcium carbonate (1 per cent.)—meat infusion broth. (This medium was first used by Bolduan in 1905).* A pure culture of a small coccus was obtained which appeared single, in pairs, and in clusters. It was flattened on the juxtaposed surfaces, stained with ordinary dyes, and was Gram negative. There was no growth on ordinary media, but it grew on glucose-ascitic-agar, ascitic-agar, rabbit-serum-agar, and Conradi-Drigalski's medium. The colonies looked like those of the gonococcus.

October 18, 1911. Dilutions of Torrey's polyvalent antigonococci-serum were made with normal saline solution containing ½ per cent. of sodium citrate. Then a suspension of the organism to be identified was made from two tubes of a 48-hour growth an ascitic-agar and glucose-agar slant to which normal saline solution containing ½ per cent. of sodium citrate was added. This was shaken in sealed tubes for two hours, and centrifugalized at lowest speed for one minute to remove clumps which might still have been present. Equal parts of the dilutions of the serum and of the suspension of the coccus were mixed in agglutination tubes. These were put in the incubator for two hours and then in the icebox for 18 hours, after which time there was a grayish white sediment and a clear supernatant fluid in the tubes containing dilutions of the serum of 1:20, 30, and 40. This was the final proof that the organism in question was a gonococcus.

Now injections of Torrey's antigonococci-serum were given. The temperature came down to the normal, but the patient died five days after the beginning of the treatment.

An autopsy could not be obtained, but after the correct diagnosis by the bacteriological examination of the blood had been made, the husband admitted having had gonorrheal urethritis some time ago, and this condition was probably not yet healed.†

*Conclusion.*—The slight systolic murmur noticed on admission was without doubt the result of the attack of acute articular rheumatism at the age of twelve. It became louder and blowing in the course of the disease, probably due to gonorrheal vegetations on the mitral valve. The joint symptoms were only slight except during the 5th week when they assumed the character of an acute synovitis of both knees. The blood culture yielded a pure growth of a micrococcus which by all its tests proved to be a gonococcus. This case is therefore one of a pure gonococcus septicemia complicated by endocarditis and arthritis.

## COMPARISON OF INTERNAL AND EXTERNAL URETHROTOMIES FOR TIGHT STRICTURES OF THE MALE.

By CHARLES AUBREY BUCKLIN, M.A., M.D.,

GLASGOW, SCOTLAND.

There was invented by Otis a dilating urethrotome for thoroughly performing internal urethrotomy; this form of instrument is the only one capable of thus dividing a stricture internally. There was also invented by Otis a urethrometer for deciding when a stricture of large caliber existed, and when internal urethrotomy was performed, for demonstrating that the stricture had been thoroughly divided.

This dilating urethrotome cannot be introduced through tight strictures until after a staff urethrotome (as the Maisonneuve) or a divulsor (as the Thompson) has first been used. The use of either of these instruments in the urethra gives greater cause for subsequent annoying complications. It causes the penis to be abnormally curved during erection, after internal urethrotomy. Cases have been frequently observed where a corkscrew-tipped whalebone bougie could be readily introduced, when neither a Maisonneuve urethrotome nor a Thompson divulsor could be made to follow the bougie through the stricture. Internal urethrotomy has often failed to relieve strictures of the male urethra, besides being frequently attended by the above complication.

Clinical experience has demonstrated that a perfect internal urethrotomy which was over one inch in length could not be performed that was not as a result of the injury caused by this operation to the superior portions of the urethra, followed by the complication of a deforming curvature of the penis during erection. Admitting that internal urethrotomy has been performed with any of the urethrotomes that have been popular during the past, it has been necessary to divide, thoroughly, the entire band of connective tissue forming the stricture before any satisfactory results could be attained from this operation. This connective tissue is excessively contractile unless thoroughly divided. Notwithstanding that care has been taken to avoid contraction of the stricture, this has frequently formed again after internal urethrotomy. It is claimed that external urethrotomy combined with the treatment described below has generally enabled the surgeon to avoid the complication of contraction which usually follows an attempt to relieve a tight stricture by internal urethrotomy. External urethrotomy causes no complications, no matter what the length of the urethrotomy may be. The results are perfectly satisfactory provided that care is taken to prevent contraction of the stricture after its thorough division by this method.

The steps taken in performing external urethrotomy upon strictures so tight that the patient was able to void urine only in drops have been the follow-

ing: A filiform whalebone bougie, preferably with a corkscrew tip, is carefully manipulated through the stricture as soon as the patient is on the operating table. When in position it is not removed until the operation for stricture has been completed. A tunneled, grooved, stopped-catheter is threaded onto the whalebone bougie and passed down until it impinges upon the stricture. The point of the catheter is cut down upon, care being taken to avoid cutting the whalebone bougie. The sides of the bottom of the urethra, close to the stricture, have long silk sutures passed through them, the sutures being used as retractors of the urethra. The stricture is divided by a probe-pointed canaliculous knife which is carefully introduced at one side of the introduced bougie. In cases that can urinate only one drop at a time there has never been experienced any difficulty in manipulating this bougie without force into the bladder.

This method has been practised by the author since 1875. Difficulties have been encountered in introducing the bougie when the patient's ability to pass urine has been entirely obstructed by a tight stricture. In these cases it has been found expedient to cut down onto the point of the catheter, where it encountered the stricfure, to retract the sides of the urethra, and to use condensed artificial light from a perforated concave mirror, a magnifying glass, and a fine probe by means of which the urethral opening through the stricture is sought after. The author has never failed to find the urethral opening through the stricture. Cases have arisen in which competent operators have failed to locate this opening. It then became necessary to make a suprapubic opening or one in the perineum through which the bladder is drained, and the case is then treated according to the instructions given in special surgical works.

For retaining a pervious urethra after either an internal or external urethrotomy the meatus is slit up with a probe-pointed knife on the lower side sufficiently to admit of a metallic sound being passed. The size of the latter can be determined by the urethrometer, about a No. 20 to 32 being usually required. The urethrometer may also be used for dilating the urethra. It is passed through the meatus of the urethra and through the stricture in a collapsed form. It is then dilated to the above size and withdrawn to the meatus of the urethra, where it is reduced in size and removed. Either of these methods answers the same purpose of distending the urethra. This last method does not require the meatus to be opened, which result is considered by many as being a deformity. The treatment of slitting the meatus has been found to give the best results in the treatment of these tight strictures. The dilatation of the operated urethra is repeated daily for thirty days, every second day for thirty days longer, and then weekly for an entire year. After external urethrotomy no return of the stricture has ever been experienced in which the above methods of treatment have been adhered to.

The patient or some member of the family attends to these details. The instrument used is always previously disinfected. The tendencies of the stricture to contract after all urethrotomies is the complication that requires guarding against. Local anesthesia only is required in these operations. One dram of novocaine solution of a strength of 2 per cent. is injected into the urethra in internal urethrotomy or injected hypodermically at the point operated upon in external urethrotomy. It produces in five minutes sufficient anesthesia to make these operations painless. After the administration of this drug there are no annoying symptoms of poisoning as there is with cocaine.

Moraybank, Langside.

## Medicolegal Notes.

**Evidence as to Permanency of Injury.**—A physician who has attended an injured person from the time of the accident to the trial and who has testified to the injury suffered may properly be permitted to give his opinion as to the permanency of such injury. Permanency of injuries must usually be a matter of opinion only, to give which medical experts are permitted.—Schlander v. Chicago, etc., Traction Co., 160 Ill. App. 309.

**Province of Medical Experts—Opinion from Facts, Not Decision of Facts.**—In a murder case, where the partial insanity of the defendant was in issue, it was held that the testimony of medical experts, who had no knowledge of the defendant's condition at the time of the murder, as to his condition at that time, was inadmissible, except upon a hypothetical state of facts; the province of the expert being to draw inferences from, and not to decide, the facts of the case.—State v. Hyde, South Carolina Supreme Court, 73 S. E., 180.

**Medical Evidence—Leading Questions—Physician and Patient—Disqualification as Witness.**—In an action for personal injuries it is the duty of the jury, and not of the court, to weigh the evidence of the medical, as well as that of other witnesses.

It was alleged in the plaintiff's declaration that, as a result of his injury to the shoulder, his left shoulder joint became dislocated and the ligaments, muscles, and tendons of his left shoulder were cut, torn, stretched, lacerated, and permanently injured.

A question to one of his medical witnesses, "What, if anything, has been the effect upon the spinal column from the shrinking of the muscle?" was objected to because there was nothing in the declaration about any spinal column. It was held that, as it was claimed that one of the effects from the injury to the muscles alleged in the declaration was the curvature of the spine, the testimony was proper as showing the nature and extent of the injury to the muscles.

A physician had testified on cross-examination that he was not positive that *x*-ray plates of the plaintiff showed anything abnormal. It was held that he could be asked, on re-direct examination, whether he noted in the plates the deposit of any foreign substance in the muscles.

A physician was not allowed to testify, contrary to the plaintiff's evidence, that he had treated the plaintiff for alcoholism.—Wilkins v. Detroit United Ry., Michigan Supreme Court, 135 N. W., 350.

**Expert Evidence—Probable Result of Injuries.**—In an action for injuries caused by being burned by molten iron, the plaintiff's attending physician was permitted to state that the character of the plaintiff's wound was such that a sarcoma, or eating cancer, was liable to ensue. The court recognized the general rule that an expert physician testifying to the consequences of a personal injury should be confined to probable consequences, but in the present case it did not think the physician indulged in pure speculation. The word "liable" is defined as "exposed to a certain contingency more or less probable." The word was used by the witness in the sense of probable, and was doubtless so understood by the jury. The identical phrase was used in Montgomery v. Scott, 34 Wis., 339, and upheld as a legitimate expression by a medical expert. The evidence was also competent as tending to prove acute mental suffering accompanying a physical injury. The liability to cancer must necessarily have a most depressing effect upon the injured person.—Alley v. Charlotte Pipe & Foundry Co., North Carolina Supreme Court, 74 S. E., 885.

**Obtaining Liquor on Prescription.**—On a trial of an indictment against a physician and a druggist for selling liquor without a license and for conspiracy, several witnesses testified that they bought liquors from the druggist on the prescription of the physician, and that the physician was not their family physician and had not made any physical examination on which the prescription was based. It was held that the court could not instruct the jury as a matter of law that the presumption was that the witnesses obtained the liquor and used it legitimately. In such a case it was for the jury to say for what purpose the prescriptions were given—Commonwealth v. Dudley, 46 Pa. Superior Court, 337.

## THE COAGULATION OF THE BLOOD.

THE frequency of the occurrence of thrombosis in disease, especially in typhoid fever, as has been recently pointed out, has attracted the attention of the practitioner to a phenomenon which has always had the greatest interest for the physiologist. It is pretty generally accepted that fibrin formation and the coagulation of the blood are brought about by the action of thrombin upon fibrinogen in the presence of soluble calcium salts. Fibrinogen and calcium salts are considered to be normal constituents of the plasma, but the source of the thrombin is at present a matter of controversy. Bordet and Delange have recently published (*Annales de l'Inst. Pasteur*, vol. xxvi, pp. 657 and 737) the results of several very interesting experiments designed to throw some light upon this question. They worked with blood taken from animals, chiefly monkeys, and came to the conclusion that the process of coagulation takes place somewhat according to this description: Upon contact with foreign substances or injured epithelium there suddenly appears in the plasma a substance (serozyme) which reacts with cytozyme to produce thrombin.

The cytozyme is produced by many of the tissue cells, by leucocytes, and to the greatest extent by the blood platelets. It can be extracted from any of these cells and such an extract may take the place of the cells in this reaction. Cytozyme is very resistant to heat, withstanding a temperature of 100° C. without destruction. It seems to exhibit a low grade of specificity in that it frequently acts better with the plasma of the animal from which it was obtained than with that from some other species. They also found that a neutral solution of peptone was able to take the place of the cytozyme in the production of thrombin. This is very surprising, for if an animal be injected with peptone the coagulability of its blood is enormously reduced.

The serozyme appears to be a much more mysterious substance. The authors believe that it does not exist preformed in the serum, but that it suddenly comes into existence when the need arises. Its source is wholly unknown. It is thermolabile, being destroyed by a temperature of 55° C. If the serum be shaken with barium sulphate and centrifuged, it is found that the serozyme has been absorbed by and precipitated with it. Plasma that has been treated with oxalate and then recalcified contains no serozyme, at least none that will functionate. Oxalate prevents coagulation by removing the soluble calcium salts that are necessary for the union of thrombin and fibrinogen. Citrates and concentrated salt solutions on the other hand interfere with the reaction between the serozyme and the cytozyme. If thrombin is permitted to form in some way or is added afterward clotting proceeds in a normal fashion.

If the results thus obtained outside the body can be considered comparable to those occurring within the body and if these observations can be verified, then we have been advanced a long step forward in the understanding of this most important process. Further reports of this work will be awaited with interest.

## TRACHOMA A NATIONAL PROBLEM.

THAT trachoma has a wide prevalence in this country and is a menace elsewhere than in alien immigrants, is beginning to be realized by sanitarians. It has been found to prevail to a great extent among the Indians and other natives of Alaska, where it ranks with tuberculosis and syphilis as one of the most destructive diseases to which these natives are subject. Of 1364 Alaskan Indians examined, over 7 per cent. suffered from trachoma, and nearly 3 per cent. were blind, largely as a result of trachoma. Among the American Indians also, the disease has a wide distribution, standing next in importance to tuberculosis, in certain sections of the southwest from 65 to 95 per cent. of the Indians being affected. At the trachoma hospital of the Indian Service at Phoenix, Arizona, alone, over 800 cases have been treated. It will be a surprise, however, to many to learn that trachoma in a virulent form has been found so prevalent in the mountains of Kentucky as to constitute a serious sanitary problem. Recently an investigation was made by Dr. John McMullen of the Public Health Service (Public Health Bulletin, November 9, 1912) in several mountain counties of Kentucky. Of approximately 4,000 persons examined, in this region, 500 or 12½ per cent. suffered from trachoma. Of the school children examined, from 3 to 18 per cent. were affected. Dr. McMullen says, "In examining the eyes of school children, it was my habit to request the teacher to write down the name of such pupils as had trachoma, and I was able in this manner to pick out entire families, as all usually had the disease. In many instances, the teacher informed me that the worst cases of sore eyes were not in school that day, and were often absent on account of 'sore eyes.' In one particular instance, the teacher volunteered to send for the remainder of the children and produced seven of the worst cases of trachoma I have ever seen, much like the old 'Egyptian ophthalmia' formerly seen among immigrants. The remainder of this family were either absent from home or the eyes were too acutely inflamed to make the trip to the schoolhouse possible."

Trachoma has evidently been present for many years among these native-born Americans. This initial survey of the mountain regions of Ken-

tucky would seem to indicate that trachoma will be found equally prevalent among the mountaineers of the contiguous States of Tennessee, West Virginia, Virginia, and North Carolina. In September, 1912, the usual semiannual clinic was held by Dr. J. A. Stucky, medical director of the Women's Christian Temperance Union Settlement School at Hindman, Knott County, Kentucky. These clinics are chiefly for disorders of the eye, ear, nose, and throat, although all diseases are treated. In the September clinic, 374 patients were examined, of whom 113 suffered from trachoma. Over 11 per cent. of the pupils resident in the school and 16 per cent. of the day pupils were subject to the disease. Roughly, 50 per cent. of all the patients applying to the clinic for relief were victims of trachoma or its sequelæ. Forty per cent. of the trachoma patients presented corneal complications with many cases of pannus and ulceration, 10 per cent. had trichiasis, 25 per cent. showed photophobia, and 25 per cent. suffered from defective vision, ranging from slight impairment to absolute blindness. The class of patients in this clinic was representative of the mountain districts.

For most of these mountaineers no adequate medical relief is now available. McMullen divides the relief work to be undertaken into two classes, prevention of new cases and treatment of existing cases. He considers popular education the best preventive measure. Clean and separate towels, linen, basins, etc., are as important as sanitation, clean homes, and fresh air. Stereopticon lectures, supplemented by district nurses who should hold nursing classes in schools and homes, would prove effective measures. Trachomatous children should be excluded from regular schools, and refractive errors among them should be corrected. For the more difficult problem of the cure of existing cases, time, money, and perseverance are necessary. Clinics similar to the one mentioned above could do valuable work, together with a system of movable field hospitals for cases requiring surgical treatment. McMullen makes a pertinent quotation from Dr. W. Cheatham on "Preventable Blindness," to the effect that, of the 64,000 registered blind persons in the United States, half at least are needlessly blind. Of the 6,200 in New York State in 1906, 1,084 were needlessly blind, and it was estimated that on an average the maintenance of one blind person for life by the State cost the sum of $10,000. In the Ohio State institution for the blind 67 per cent. of the blindness was due to trachoma. About a year ago in the Kentucky Institute for the Blind, 45 per cent. of the inmates owed their blindness to trachoma.

Since the New York City Board of Health has instituted systematic examination of the eyes of school-children, it has been found that from one-third to one-fourth suffered from some form of conjunctivitis, but it is probably incorrect to class a high percentage of these cases as trachoma. Dr. Charles H. May has pointed out that many of these cases present an acute or chronic catarrhal conjunctivitis with more or less follicular hypertrophy, and that these cases, if neglected, do not lead to pannus, corneal ulceration, or deformed lids. While this form of conjunctivitis is contagious, the type is constant and never changes to real trachoma.

While it is true that fewer cases of severe trachoma are now found among immigrants, still undoubted cases are fairly common. In the fiscal year 1911, 2,504 cases were certified in alien immigrants. There has been more or less criticism by those not familiar with the actual examination, that the medical examiners often fail to differentiate between true trachoma and other forms of conjunctivitis. But a careful, first-hand investigation will show that only undoubted cases, as tested by the chronicity and resistance to treatment, or by serious sequelæ, associated with a still active process, as well as by the clinical picture, are certified. Moreover, suspected cases are kept under observation and approved treatment for a period of time before certification. The disease is a sanitary menace wherever it occurs, and the immigration law properly excludes those suffering from it.

Trachoma is entitled to more consideration than it has heretofore received, as a factor tending seriously to decrease economic efficiency in its victims and indirectly in the local population among which it occurs. It is known to be communicable and is believed to be contagious. Its eradication from the United States will require knowledge and cooperation on the part of the people, and a systematic, long-continued campaign on the part of public health authorities. The U. S. Public Health Service is now conducting active relief measures for this and other diseases among the Alaskan natives, besides making a thorough study of the prevalence and best means of control of the disease among the American Indians and the mountaineers of the South, and so far as possible preventing its introduction by immigrants.

## EPIDEMICS OF SEPTIC SORE THROAT.

An epidemic of sore throats which broke out in Baltimore early in March, 1912, was in some respects so unusual as to engage the special attention of many physicians of that city. In Public Health Reports, November 22, 1912, Passed-Assistant Surgeon Wade H. Frost has a fairly exhaustive account of an investigation made by him of the epidemic. While sore throat was the most prominent of the early symptoms, the severity of the inflammation in the throat varied greatly and the marked and persistent enlargement of the cervical glands was one of the most striking features of the cases. From a bacteriological study of the outbreak made by William Royal Stokes and F. W. Hachtel of Baltimore, it appears that the organism giving rise to the infection was that described by Davis as the *Streptococcus epidemicus*.

Perhaps the most generally important phase of the epidemic in question, however, was the fact that the infection was disseminated chiefly by the milk of one of the larger dairies in Baltimore. Furthermore, and this also is a point of much moment, it is believed that the milk had become infected prior to its receipt at the pasteurizing and distributing plant in the city and that the infective

agent in all probability survived the inadequate "flash" process of pasteurization employed at that time.

An epidemic clinically similar, and due apparently to the same infective agent, occurred in Boston, in May, 1911, and was traced by Winslow (*Journal of Infectious Diseases,* January, 1912) to unpasteurized milk. Another epidemic of the same character occurred in Chicago in the winter of 1911-12. The epidemic is said to have been extensive and like that of Boston due to infection of the milk of a single large dairy. As Frost points out this rapid succession, in three widely separated cities, of extensive outbreaks of a new, or at least a previously rare and very serious infectious disease should direct the attention of the public health authorities to a grave consideration of its cause and prevention.

The main lesson to be learned from this epidemic is that in order to guard the public against similar outbreaks milk must be protected against infection in the most rigid manner. The other lesson is, as Winslow showed in the Boston epidemic, that the so-called commercial pasteurization is a delusion. Indeed, the method is worse than useless, for it gives confidence in a milk that may be seriously infected and thus be the means of spreading an epidemic widely. All milk that is pasteurized should undergo this process thoroughly, and in order to achieve this object it may be necessary to insist that no milk should be retailed under the name of pasteurized milk unless it has been so treated under official supervision.

### Difficulties in the Diagnosis of Diseases of the Ductless Glands.

The puzzling correlation of two or more ductless glands in the pathology of individual cases will doubtless do much to offset the original feeling of optimism born of the results of thyroid feeding in various diseases. Thus at a recent medical gathering in Königsberg (*Münchener medizinische Wochenschrift,* November 19) Goldstein related an experience in point. He performed hysterectomy and castration for myoma in a woman aged 41. Nine years later she presented symptoms suggesting acromegaly. The *x*-ray showed no abnormality of the hypophysis. It was learned that in childhood the woman had shown a similar acromegalic tendency which had evidently been outgrown. The castration had seemingly reawakened this tendency. The enlargement involved the hands and feet, nose and chin. The same author presented several patients who were apparently afflicted with dystrophia adiposogenitalis, a supposed hypophysis syndrome; yet the *x*-rays showed that the latter gland was normal. These patients presented a well marked triad —imbecility, pathological accumulation of fat, and hypoplastic genitals. Such cases force us to assume a primary embryonal hypoplasia which according as it involves one or another ductless gland, or more than one, produces a clinical picture which may be more or less misleading. We know, for example, that in a true cretin the thyroid is involved secondarily. We can help him to some extent when young by thyroid feeding, but cannot thereby reach the actual source of the developmental anomaly, nor greatly benefit the adult cretin.

### Folk Neuroses.

This term has recently been introduced to designate those nervous abnormalities which are so common as to be almost universal. A paper on the subject was read recently by Rubin at a medical meeting in Essen-Ruhr (*Berliner klinische Wochenschrift,* November 25). The folk neuroses comprise simple nervousness, neurasthenia, hysteria, and hypochondria. The condition must be approached both in the individual and in the community. It is unsatisfactory to deal with the individual case and efforts should be directed to wholesale hygiene by the promotion of sports and games, athletics, out-of-door life, school hygiene, etc. One strong-nerved member of the Society, in commenting on this paper, was so old fashioned as to deny the existence of a general tendency to functional nervous diseases of this class and made bold to imply that the subjects of these "folk neuroses" were either masturbators or malingerers. He was very properly and pointedly rebuked by several of his fellow members.

## News of the Week.

**Eye Diseases in the Schools.**—Urging that the responsibility for the physical examination of all school children in New York be placed upon the Department of Education, instead of being divided as at present between that department and the Department of Health, Dr. W. M. Richards of this city recently reported the results of his examination of forty deficient children in the public schools. From his examination and from a study of the numbers of children who fail to advance regularly he concludes that there are 78,000 children in the public schools of New York with defective vision, and that 80 per cent. of these could be greatly helped by proper care of the eyes. He recommends that the entire care of the school children, mental, moral, and physical be vested in the Department of Education and that all backward children be examined by carefully trained physicians and defects of structure or habit corrected.

**For Quieter Streets.**—The police of Berlin, Germany, have recently issued regulations intended to make the streets of the city quieter and cleaner. The regulations, which will be put in force on April 13, provide that the windows and doors of houses, shops, etc., in which music is being played shall be kept closed: that no whistling, singing, shouting, or loud talking on the streets shall be allowed; that teamsters shall not drive in a manner calculated to produce ear-splitting noises; that no paper, fruit skins, etc., shall be thrown into the streets; that the dragging of women's skirts or anything else capable of producing dust shall be forbidden; and that persons carrying umbrellas or canes shall not carry or swing them in any manner likely to imperil the safety of another person. One wonders how far such ordinances could be enforced by the police of New York.

**"Health Bookkeeping."**—The Health Committee of the Association of Life Insurance Presidents has recently made a report urging a campaign for the purpose of securing better vital statistics and registration in those States below the standard set by the United States Government. The registration of vital statistics is called "health bookkeeping," and it is believed that this method is essential in improving health conditions and prolonging life, and

that publicity is the most effective agent that can be employed in any reform, far more so than mere mandatory legislation. The association will cooperate with the United States Census Bureau, which is advocating a standard form of registration throughout the States.

**For Medical Research.**—The Faculty of Medicine of the University of Toronto, Canada, has received an endowment fund for medical research, the income of which will probably amount to $25,000 a year.

**Street Accidents.**—November was a dangerous month in New York City streets, according to the reports of the Public Service Commisson, which show that there were 5,783 accidents of all sorts connected with the street cars during the month, while the number last year was only 5,291. Of these, 19 were classed as serious, thirty-two persons were killed, seven received fractured skulls, thirty-eight had their legs broken, and the legs of two were cut off.

**Another Tuberculosis Hospital.**—The Herkimer County, New York, Board of Supervisors on December 20 voted to establish a county hospital for the treatment and care of persons suffering from tuberculosis. A site near Fulton Chain will be secured and improved as soon as possible. This is the twenty-eighth county in the State to take steps to provide hospital care for tuberculosis patients.

**Cholera Epidemic.**—Reports have been received in London of an alarming epidemic of cholera in Mecca, where 10,000 pilgrims have gathered. It is said that from December 23 to 27 there were 1,714 deaths from the disease.

**Scarlet Fever Prevalent.**—A small epidemic of scarlet fever in and about Westbury, L. I., has caused the health officer to order the closing of all the schools, including the Sunday schools, for at least two weeks. Sixteen cases were reported on December 28.

**Eugenic Reforms.**—The sterilization of persons convicted of certain crimes or judged unfit to have offspring and the creation of a State Board of Eugenics by which marriages shall be controlled and licenses to marry issued, are advocated by the Utah State Board of Insanity in a recent report to the Governor of the State.

**British Doctors Yielding.**—The British Government having made it clear that it was not disposed to offer any further concessions to the physicians in regard to the Insurance Act, a break in the ranks of the doctors is reported to have occurred and many of them are agreeing to accept the terms offered by the Chancellor of the Exchequer. Eight members of the Council of the British Medical Association are said to have resigned because of disapproval of the tactics of the Association.

**Anti-Opium Manifesto.**—Following the receipt of a note from the British Government protesting against the attitude of the provinces as regards the trade in opium, the Chinese Government has issued a manifesto reiterating its desire to suppress the evil.

**Centenarian Dead.**—Having worked daily as a servant and scrubwoman up to the age of one hundred, Ellen Horgan of New York died recently in her one hundred and fifth year.

**City Death Rate.**—During the week ending December 21 there were in New York City a total of 1,481 deaths, giving a death rate of 14.98, as compared with 1,310 deaths and a rate of 13.71 in the same week of 1911. The increase was confined entirely to mortality among adults.

**Railroads and Smallpox.**—Because of the prevalence of smallpox along the course of the New York, Ontario & Western Railroad, the New York State Commissioner of Health has urged the vaccination of all railroad employees, to whom he believes the spread of the disease may be largely traced. The officials of the railroad in question have instructed their employees to comply with the Commissioner's suggestion.

**Physicians' League of Brooklyn.**—At a recent meeting of this society the following officers were elected for the ensuing year: *President,* Dr. Thomas Dixon; *Vice-President,* Dr. Martin L. Bodkin; *Recording Secretary,* Dr. Charles Dumey; *Treasurer,* Dr. Melvin Sheldon; *Corresponding Secretary,* Dr. David Davidson.

**Gifts to Charities.**—The German Hospital and Dispensary of New York receives a bequest of $2,000 by the will of the late Mr. Louis Schaefer of this city.

The German Hospital also receives a bequest of $3,000 by the will of the late Mr. Peter Doelger, who also left $6,000 to the Little Sisters of the Poor for St. Francis Hospital, and $1,000 to Mount Sinai Hospital.

St. Mary's Hospital, Brooklyn, has received from Mr. Robert Furey of that city a gift of $100,000 to be used in paying off the mortgage on the building, and from Mr. James Shevlin a gift of $50,000 for the erection of a nurses' home.

**Obituary Notes.**—Dr. Edward Leroy Oatman of New York and Brooklyn, a graduate of the Bellevue Hospital Medical College, New York, in 1879, a member of the American Medical Association, the New York State and Kings County Medical Societies, the New York Academy of Medicine, surgeon to the Manhattan Eye, Ear, and Throat Hospital and to the Brooklyn Eye and Ear Hospital, and consulting surgeon to the Nyack Hospital and to St. Mary's Hospital of Waterbury, Conn., died at his home in Brooklyn on December 26, aged 59 years.

Dr. John A. Axline of Noblesville, Ind., a graduate of the Medical College of Ohio, Cincinnati, in 1873, and a member of the American Medical Association, and the Indiana State and Hamilton County Medical Societies, died at his home on December 9, aged 65 years.

Dr. Elizabeth S. Mitchell of Montreal, Quebec, a graduate of Queen's University Medical Faculty, Kingston, Ontario, in 1888, Licentiate of the Royal College of Surgeons and of the Royal College of Physicians, Edinburgh, Licentiate of the Royal Faculty of Physicians and Surgeons of Glasgow, and Licentiate of the Apothecaries' Society of London, 1888, died in Nashua, N. H., after a short illness, on November 30.

The Rev. Albert C. Bunn, M.D., a graduate of the Medical Department of the University of Buffalo in 1867, the first medical missionary to the interior of China, serving from 1874 to 1879 at Wuchang, where he established St. Peter's Hospital and the Elizabeth Bunn Memorial Hospital, and more recently a priest in the Episcopal Church, died at Asheville, N. C., on December 24, aged 67 years.

Dr. Christopher C. Miller of Detroit, Mich., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1868, one of the founders of the Detroit Homeopathic College and for some years its president, a member of the Michigan State Homeopathic Medical Society and of the American

Institute of Homeopathy, and ex-president of the board of directors of Grace Hospital, died at his home on December 17, aged 66 years.

Dr. John D. Pfister of Creve Cœur, Mo., a graduate of the Missouri Medical College, St. Louis, in 1888, and a member of the Missouri State and St. Louis County Medical Societies, died at his home on December 11, as the result of injuries received in an accident, at the age of 49 years.

Dr. Herbert Augustine Longan of Kansas City, Mo., a graduate of the Louisville (Ky.) Medical College in 1880, police surgeon of Kansas City from 1897 to 1907, and formerly connected with the Kansas City Medical College, died in Houston, Texas, after a long illness, on December 18, aged 61 years.

Dr. William Standing of St. Louis, Mo., a graduate of the Missouri Medical College, St. Louis, in 1871, and formerly a member of the faculty of the St. Louis College of Physicians and Surgeons, died at his home from pneumonia, after a short illness, on December 15, aged 66 years.

Dr. Everitt James Bergen of Washington, N. J., a graduate of the New York University Medical College in 1877, died at his home of heart disease on December 24, aged 66 years.

Dr. John Thomas Sidener of Columbus, Ohio, a graduate of the Starling Medical College, Cincinnati, in 1882, died at his home on December 16, aged 56 years.

## Correspondence.

### OUR LONDON LETTER.

(From Our Regular Correspondent.)

VOTING ON THE INSURANCE CRISIS—DISSENTIENTS MOVING—CHANCELLOR MEETS HOSPITAL CHAIRMEN—SCOTTISH QUALIFYING BODIES' STATEMENT—ANESTHESIA IN AMERICA—INTRAOCULAR PRESSURE—ANOTHER HOSPITAL FOR LONDON—OBITUARY.

London, December 20, 1912.

All the week voting has been going on as to accepting or rejecting service under the Insurance Act. Discussion has also continued and unhappily sharp differences of opinion have been developed. The figures will be reported to the special representative meeting of the British Medical Association to-morrow. This body will have to come to a decision which may be of the utmost importance to the association and indeed to the whole profession. Probably the meeting will be prolonged and perhaps may be adjourned until Monday. Up to this evening the following figures have been ascertained and though a few more may have come in by to-morrow the result is not likely to be greatly affected. The majority for rejection is a large one, 9,374 members and 1,935 non-members of the British Medical Association as against 1,968 members and 454 non-members. Thus out of the total number of members, which is about 17,000, the votes recorded are 11,342; where are the others? Further, out of the total number of qualified practitioners in the United Kingdom, about 29,500, only 13,731 have voted. These figures, however, display a greater degree of union in the profession than has ever been known. It should be remembered, however, that although less than half the qualified men have taken the trouble to vote the number must be great of those who have been unavoidably prevented and still greater of those whom the act does not concern as they do not engage in contract practice. Then it is not to be forgotten that 27,000 out of the 29,500 signed a pledge not to make individual agreements unapproved by the profession or the local medical committees. Nevertheless the slight concessions made, which on strict examination seem to have little reality, have caused hesitation among many, and a few have broken away, as I informed you, and set up another society to advocate submission and persuade others that the pledge is not binding. Of course the Socialists are delighted as they want to see a full time State service and will back up Mr. Lloyd George in his attempt to reduce the profession to the position of a gigantic medical club under the control of the proletariat and secure their support at the next election. If, as he declares, such socialistic schemes would be beneficial to the whole community he should begin on the legal profession—to which he was brought up and about which he may be supposed to know something, though he is wholly ignorant of the condition of the medical profession.

Today the statements of those desirous of taking service reach me. They protest against the "tyranny" they pretend is being exercised and declare "no bullying or threats are hard enough" to be used against them. They speak of "gross intimidation" but in a p.s. ask me for details of any intimidation to which I may be subjected. On the other hand they express "deep gratitude" to Dr. Lauriston Shaw, who seems to be their leader, although he is one of the council of the British Medical Association and chairman of its ethical committee. In May he was "amazed at the profession's moderation." This month he presided at the meeting of the dissentients. They have written to the Chancellor to ask if those who go on the panels will be protected against boycott or intimidation. Mr. Lloyd George has promptly replied in the affirmative though he significantly remarks "I can hardly believe that any such methods could be employed" in the case, but if they should be the government will do all in their power.

Many other points have been raised in the discussions among them how far the pledge is binding. Every man is the guardian of his own honor. Some are contending that the conditions have changed but others deny this.

On Tuesday the Chancellor of the Exchequer had an interview with the chairmen of the larger London hospitals. The meeting was understood to be private and merely for an exchange of views as to the effect of the Insurance Act on voluntary hospitals. An official statement was, however, issued to the press in which it is said the Chancellor explained that the main work of hospitals would not be affected as the act only affords the treatment given by general practitioners. He said the hospital question had not been overlooked in framing the act and it had been thought better to avoid any steps that would imperil the voluntary nature of the great hospitals. Some points were submitted to him as to the financial position of the hospitals and he promised to consider them. The report seems to point to the inference that the meeting took place on the understanding—at any rate on the Chancellor's side—that the profession would administer the act. Further, it may be supposed that the lines on which hospitals could continue their work were discussed. The in-patients' department may not be affected if the finances are not injured, but there is a probability of restriction of the num-

ber of out-patients which have long been regarded as reaching an abuse. Another view commonly expressed is that Mr. George only wanted to persuade the hospital chairmen to lend their influence with the profession in favor of the scheme.

The three qualifying bodies of Scotland (the R. C. P. and R. C. S. Edin. and Royal Faculty of Glasgow) have unitedly issued a criticism of the concessions made by the Chancellor. They declare nothing but an amending act can place the provisions on a satisfactory basis and that if members are prepared to accept service on the terms offered, the "Royal Colleges and Royal Faculty, while not attempting to dissuade them, cannot be parties to an agreement which is derogatory to the status of the profession." In their view the act "will perpetuate some of the worst features of club practice." They are assured that many practitioners agree with their view and they "wish it to be understood that the profession in adhering to that view may count on their sympathy and support."

We have had a discussion on the administration of anesthetics in America which may interest you. It was opened in the Section of the Royal Society of Medicine devoted to the subject by Mrs. Berry who described the method at the Mayo Clinic at Rochester, Minn., as observed in a recent visit. This will be familiar to your readers, so I may pass on to the discussion which followed the paper, premising merely that it was highly eulogistic and even stated that many hospitals prefer nurses specially trained at Rochester to their house surgeons, who usually only occupy the post for a short time. Photos of the open ether administration were shown by Mr. Paterson. Dr. Blumfeld, presiding, said the light anesthesia mentioned in the paper would not satisfy surgeons here, and he did not think its production called for so much skill as the author stated. Mr. Bellamy Gardner thought if ether increased the hemorrhage it should not be employed in operations for cleft palate or adenoids. He said relaxation of the abdominal muscles ought not to be produced and was never necessary if proper restrictions were used. Dr. A. L. Flemming thought the opinion that deep anesthesia prevented shock was responsible for many accidents. It was well this opinion was dying out. Mr. George Gask disputed the excellence of American practice and said the Mayo clinic was not a fair example, for it stood far above every other place in the United States as a surgical center. He had visited other places in America and considered the anesthesia below the London hospital standard. He thought, too, the surgeons interfered with the anesthetists far more in the States than in London. Open ether was given—and given well—at the Mayo clinic for everything. He did not know whether the climate accounted for the freedom from ether bronchitis in America. One thing to be remembered was that many patients traveled hundreds of miles to Rochester, so they did not get there the horrible fulminating cases seen in London hospitals. Dr. Silk said the type of patient seen at the Mayo clinic was scarcely that of the usual hospital patient. Dr. D. Powell said we might learn a lot about open ether from Americans, as they might from us about other anesthetics, and he had no doubt they would be glad to have a class of such expert anesthetists as we have. Mr. Carter Braine spoke of the risk of employing unqualified persons as anesthetists. Mr. Paterson said we learned more from Americans than they from us. Open ether was not so well given here as on the other side. He had become converted to their method and now rarely gave chloroform. Mr. Pridaux sent for inspection a face piece he had designed for use for patients who had lost many teeth.

The Ophthalmological Section has been considering the physiology of Intraocular Pressure, introduced by Dr. Leonard Hill. He and Drs. Flack and Thomson Henderson had worked together and the subject had been before the Royal Society. The flow in the retinal vessels was known to cease when the pressure reached that of the general arterial blood. On puncturing a cat's cornea and then gently pressing its abdomen Drs. Hill and Flack found the iris on that side the seat of hemorrhage, which came from the capillaries. Their explanation was that the normal aqueous pressure exactly balanced that of the capillaries. Intraocular tension had been said to be due to elasticity of the lens, but it had none, for when removed it was a soft pudding-like body. In the act of accommodation the muscle contracted, but continued of the same volume, moving inward as shown by Thomson Henderson, allowing the fluid to pass from the front of the lens into the spaces of the ciliary body or of the cribriform ligament and into the suprachoroidal space. Some remarks were made by members expressing difference of view, but the discussion was adjourned.

We are to have another hospital in London, though many people think it is not required. The plea for it is that in South London there is room for it. The special feature is that it shall be exclusively officered by medical women. An anonymous donor has sent £25,000 to the promoters to purchase a site and build.

Dr. C. Theodore Williams, M.V.O., F.R.C.P., consulting physician to St. George's Hospital and to the Brompton Hospital for Consumptives, died on the 15th inst. in his seventy-fourth year. He was an Oxford man and honorary fellow of Pembroke College. He gave the Lettsomian lectures in 1877 on "Climate in Consumption," and in 1887 published a volume on "Pulmonary Consumption." He contributed largely on similar subjects to the Medico-Chirurgical Transactions and Quain's Dictionary, as well as to the societies, his work extending almost to the present time. In 1902 he was a vice-president of the Congress on Tuberculosis and opened the discussion on climatology. He was one of the founders of the Davos Sanatorium, and on King Edward's committee appointed to study the subject of sanatoria.

## NINTH ANNUAL MEETING OF THE PHILIPPINE ISLANDS MEDICAL ASSOCIATION.

(From Our Regular Correspondent.)

MANILA, November 6, 1912.

THE third session of the Philippine Islands Medical Association began with a surgical clinic, from 7.30 to 10.30 a. m., at the Philippine General Hospital, by Doctors Gilman and Schiffbauer. The first paper read was "The Surgical Treatment of Acute Gonorrheal Orchitis and Epididymitis," by Dr. B. K. Burdette.

The second paper, entitled "The Outbreak of Plague in Manila during 1912" was read by Dr. Victor G. Heiser. In this he gave a brief statement of fact with regard to the principal occur-

rences in connection with the present outbreak of plague in the Philippine Islands, and called attention to the fact that after an absence of six years in human beings and five years among rats, plague again made its appearance in the Philippine Islands on June 19, 1912. During the interim in which plague was absent from the Philippines, the disease was frequently encountered on arriving vessels, but was invariably stamped out at quarantine. Last spring a most insidious form of the disease was found upon a number of vessels. The first case occurred in the person of the Chinese cook on the S.S. *Zafiro,* which arrived April 5, and after the vessel had been in port for 24 hours. The victim was seen on deck at 10 p. m. the night previous, but at 6 o'clock the next morning (April 6) he was found dead. The autopsy showed this to be a case of pneumonic plague. The second case occurred on April 7 on the S.S. *Loongsang.* On investigation the captain of the ship stated that on the afternoon of the previous day, while a Chinese member of the crew was hauling on a rope, he fell over in a faint, was placed in a chair and died in a few hours. The autopsy showed that he died of pneumonic plague. The third case was encountered at the Mariveles Quarantine Station in the person of a Chinaman who, at the time of his arrival, presented no other symptoms except elevation of temperature. During the week which followed the only symptom that he showed was a continued fever, and during all this interim he constantly insisted that he was not ill, and demanded that he be discharged from the hospital. On the afternoon of the eighth day slight enlargements were noted in the axilla and cervical region, and on the morning of the ninth day he died of plague, the diagnosis being bacteriologically confirmed. The first case of human plague in Manila occurred on June 19 in the person of a Filipino watchman in the Chinese district, who lived on Calle Antonio Rivera. The history of the case showed that he had been a permanent resident of Manila for years; had not associated with persons who had been in Hongkong or other plague-infected places, and lived far from the waterfront, and in general, his history was negative. No deductions could be drawn as to the manner in which he contracted the infection. The second case occurred in a Filipino woman who lived on Calle Azcarraga, far removed from the first case, and clinically presented no buboes, and it was only after most persistent search at autopsy that small glandular enlargements were found in the femoral region. Smears made from these as well as the spleen showed plague-like bacilli, and inoculation experiments resulted positively for plague. A rat-catching campaign was immediately started, and rats were caught at the rate of 3000 per month, but it was not until August 31 that an infected rat was found. The sanitary measures employed were the isolation of the sick at the San Lazaro Hospital; the sprinkling of infected premises with kerosene, and later, disinfecting with some form of emulsified coal-tar product; rat-proofing of houses and premises, and insistence on the use of metal garbage cans, and in general, the sanitary improvement of the districts in which cases occurred. He showed a map of the cases, and the intimate relationship between human and rat plague was graphically shown; in other words, where there had been disease among human beings there was invariably found plague among rats. The most probable factors concerned in the introduction of plague into the Philippines were rats that actually arrived in cargo. It was not likely, he thought, that the plague rats came ashore by the gangways, ropes, or cargo-chutes, because the rats along the waterfront were still negative for plague, and the wharves were practically free from rats at all times. On account of the fact that cargo, passengers, rats, vermin, fleas, etc., could arrive from badly plague-infected centers within the period of five days showed that it was possible for the disease to be imported well within the incubation period. It was possible that it might have been introduced by rats with china-ware, glass-ware, etc., which is packed in straw or hay and which is imported from Japan.

The next paper was entitled "Bacteriological Observations Made During the Outbreak of Plague in Manila in 1912," by Dr. Otto Schoebl. In this the author gave the technique for detecting plague, both microscopically and biologically, in man and rat. This corresponded closely to that which was published recently in the Public Health reports. In two instances plague bacilli had been recovered from skin lesions, one of which was apparently a flea-bite. Plague bacilli had been recovered a number of times from blood, and almost invariably in the fluid which is aspirated from plague glands during life.

The next paper was entitled "The Outbreak of Plague in Iloilo in 1912," by Dr. Carroll Fox. In this the author drew attention to the fact that in this outbreak the first case occurred on July 5, and the last on September 17, a total of nine cases having occurred. In spite of an active rat-catching campaign which had been carried on since the first human cases occurred, no infected rats had been found. The author suggested the possibility of plague having been introduced into Iloilo from Manila, or perhaps from Hongkong or other infected place, by means of bed-bugs. He was not prepared, however, to make out a scientific case in this regard.

In the discussion which followed upon the three plague papers which were read, Dr. Gomez desired to know whether it was not probable that human cases had been overlooked between the time that the case occurred at Quarantine, in April, and the time that the first case was recognized in Manila, in June. Dr. Butler desired to have more specific information as to whether there was any evidence that a bedbug having recently bitten a person suffering from plague could not inoculate a non-infected individual with its proboscis. Dr. Ashburn desired to know whether the petroleum was sprinkled around premises with the idea of its being a germicide or simply an insecticide; also, whether the cargo which arrived on the infected steamers *Zafiro* and *Loongsang* had been traced to its destination, with the view of determining possible infection from it being responsible for the first human cases. He requested information as to whether definite proof was available that the deaths among rats in the warehouses of the Manila Railroad Company were due to plague, and also wanted to know whether there was any evidence whether there were other factors beyond flea or bedbug transmission which might be responsible for the outbreak of the disease.

Dr. Gibson called attention to the fact that it had been the frequent experience of the New York Board of Health that guinea pigs and other laboratory animals were bitten by bedbugs, from which he wanted to know whether there were any data available that bedbugs might bite infected rats and

thus convey the infection to human beings. Dr. Jackson called attention to the desirability of freeing the whole city from rats. He pointed out the difficulties which lay in the way, and that it was an ideal the accomplishment of which should be worked for. He emphasized the remarks made in the paper of Dr. Heiser, that the most successful method of catching rats in Manila was found to be the bait of rice which had been boiled with arsenous acid in the proportions of 5 to 1.

Dr. Yeamans called attention to the old formula of plaster of Paris and flour, which, he stated, had been successfully used in San Francisco. He also suggested that rats might be successfully caught by having a barrel half full of water, and with a tilting lid, and having inside a rock which just projected above the water. The rat stepped on the tilting lid, was dropped into the water, climbed up on the stone and lustily called for help, which brought many other rats to the trap, who likewise fell into the water and eventually were drowned.

In summing up the discussion, Dr. Heiser stated that the food cargoes which arrived from plague-infected ports were generally distributed by some hundreds of carriers within an hour or two after the cargo was placed on the dock in Manila, and it was obviously impossible to trace individual packages of cargo; that in the cases of the cargo from the *Loongsang* and *Zafiro,* it was inspected, but no evidences of rat infestation were noted, and it was, therefore, promptly released. Dead rats which were found around the Manila Railroad Company's station were, unfortunately, not sent to the laboratory, with the exception of one rat which was found upon the day upon which the Bureau of Health was notified of the mortality among rats. This was reported as very suspicious for plague, but up to this time the complete biological report was not available; the indications were, however, that it would result positively. In sprinkling kerosene about premises of infected houses, the idea was to use the same as an insecticide, or pulicide, and not as a disinfectant. By this means an infected building or premises could be quickly made safe for the entrance of laborers, and after this, by the use of an emulsion of a coal-tar product, actual disinfection could be carried out. In addition to other factors being concerned in the transmission of plague, he replied that the map of the present outbreak seemed to furnish almost conclusive proof that the disease is intimately associated with rat-plague. Furthermore, the facts that the plague was confined to the north side of the river, that people crossed the bridges freely, and that the rats did not cross the bridges, would seem to offer additional proof that the rats were the principal factor concerned in the transmission of the disease. He stated, however, that in the first case found there were abscesses of the tonsils, and the principal buboes found were in the cervical region, and called attention to the fact that McCoy had recently reported from Hawaii that the cases of plague which had occurred during the past few years in Hawaii, in isolated places, almost always showed the largest glandular involvement in the cervical region. As to other factors concerned, he invited attention to the recent report by a Russian observer, that bedbugs that had bitten plague-infected individuals were crushed in the bedsheet which was thrown aside, and the blood thereon, examined six months later, was found to contain virile plague bacilli, showing, of course, that there might be other factors concerned in its transmission, but on account of the strong evidence that the outbreak which occurred in the warehouses of the Manila Railroad Company, in which thirteen cases occurred in two days, and which was immediately brought to a close by simply exterminating rats and sprinkling the premises with kerosene, was intimately associated with rats, it was thought that these were the factors most concerned in the outbreak in Manila.

In reply to Dr. Jackson, he cited the example of Tokio, in which some millions of yen were spent over a period of three years in an attempt to free that city from rats, and at the end of that period the rats were, apparently, as numerous as when the eradicating campaign began. While it was a grand ideal to attempt to destroy all the rats of a city, yet this could scarcely be done as a Government measure, because the amount of funds that would be necessary would be prohibitive, and the only hope for eventually eradicating all rats from the city was an engineering problem which consisted in building the rats out of existence, that is, to make all premises practically rat-proof. For the purpose of combating plague, he believed that the best results could be obtained by centering all forces available upon sections in which infected rats had been found, with the hope of stamping out the disease among them. This method had been successfully used in Manila in 1906, and resulted in the complete eradication of plague after all other measures which had been used over the period of the seven previous years had failed.

At the afternoon session, which took place at 2 o'clock, the first paper read was entitled "Intra-orbital Tumors and Their Operative Consideration," by Dr. Reinhard Rembe. The author showed a large series of photographs and explained his technique of removing the outer wall of the orbit in order to make the orbital tumor accessible.

The next paper was entitled "Notes on Some Recent Surgical Cases at the Naval Hospital, Cañacao," by Dr. N. J. Blackwood. In this the author gave a report on a case of typhoid perforation which had been successfully operated upon, and a number of appendicitis and gall-stone cases.

The next paper was entitled "A Review of the Literature on Cultivation of Fresh Tissues in Various Media," by Dr. R. M. Lhamon. In this the author gave a review of the recent literature and showed specimens of active tissue which were grown in Harrison's medium.

The next paper was entitled "Diagnosis of Appendicitis," by Dr. P. K. Gilman. The author especially pointed out the fact that appendicitis was a disease of many variable symptoms, and the removal of the appendix, even in those cases which showed slight symptoms, often resulted in great improvement in the patient's condition. He related a number of cases in which, for instance, chronic constipation had been present, and, after the removal of the appendix, it disappeared completely. In others there had been nervousness and alternate attacks of diarrhea and constipation, all of which symptoms were relieved after the appendix was removed.

The next paper, "Treatment of Acute Appendicitis," was by Dr. Hans Schiffbauer. In this the author gave a brief description of the treatment which is used at the Philippine General Hospital for these cases.

The last paper was entitled "A Preliminary Report of the First Five Cases of Cesarean Section in the Treatment of Placenta Previa Performed

in the Philippine Islands," by Dr. Fernando Calderon. The author stated that the operation was first done in the Philippines at the old Civil Hospital in 1904, and the last case was the one which had been operated upon last week by him. The results, in all cases, were thoroughly satisfactory, and the mortality compared favorably with that obtained by other operators throughout the world.

## THE ANCON HOSPITAL.

To the Editor of the Medical Record:

Sir:—In an editorial article in the November 30 number of the Medical Record on "Relapsing Fever at Panama," you state that: "This outbreak illustrates forcibly the need of a hospital in the Canal Zone so situated and conducted that it could utilize the wealth of new clinical material which will be found there for study and observation." The Isthmian Canal Commission has had in operation for more than eight years such a hospital, which now has over 1,500 beds and treats over 20,000 cases a year, and in connection with this hospital there is a large and well-equipped laboratory where research work is being done. A brief examination of the many excellent papers which have been contributed by the staff of the hospital for current publications, as well as many others which are published in the proceedings of the Canal Zone Medical Association, will show that the wealth of clinical material is being fully utilized for study and observation. In this connection I may state that the fever referred to by Dr. Perry in his report is not a relapsing fever due to spirochetes.

Chas. F. Morse, Superintendent.

5. The Treatment of Pulmonary Tuberculosis by Artificial Pneumothorax, According to the Method of Forlanini. G. M. Balboni.

**2. Chronic Alveolar Osteomyelitis.**—L. S. Medalia divides the treatment of the condition into three parts, as follows: Vaccine therapy, systemic treatment, and local treatment. The combination of stock with autogenous vaccines was found to be more efficacious than either alone. The dose varied from 50 to 100 million of pneumococcus vaccine and from 50 to 300 million of *Staphylococcus aureus* vaccine, except where the latter was used at the same time for a staphylococcus skin infection (acne, furunculosis) when its dose was increased. The dose of the streptococcus vaccine varied from 15 to 75 million. The interval varied from 5 days in the beginning to 8 and 14 days or longer later, according to the amelioration of the local condition. Systemic treatment was principally attention to diet, the development of a water-drinking habit (2 quarts daily), proper personal hygiene and attention to proper elimination. The local treatment was left entirely in the hands of the dentist, who removed calculi and necrotic bone when present, kept the teeth free from tartar, established free drainage of pockets and instructed the patient in the home care of the teeth. The dentist found it necessary to delay local treatment in many cases in which the teeth were too loose and gums too tender for instrumentation. Such patients were followed up by vaccine treatment first until the teeth were rendered tighter and the gums less inflamed and less tender. Mild antiseptics were also advised, mostly for the purpose of calling attention to the cleaning of the teeth and tartar deposits.

**4. X-Ray Diagnosis of Gastrointestinal Conditions.**—P. Brown states that this method is but one factor making for diagnostic success in any given case. The practitioner of the future is in danger, through just such helpful agents as these, of becoming a clinical scientist instead of a scientific clinician. His primary mission is still entered upon at the bedside and at the bedside he has little else to aid him than had his predecessors of the earlier days—his five wits. Let him, therefore, use them, and then he will be able to stretch forth his hand toward the laboratory, not beseechingly, as one who is helpless, but with the authority born of knowledge, as becomes a master.

11. Carcinoma of the Uterus. T. S. Cullen.

**1. Defects in the Central Visual Field.**—P. Fridenberg calls attention to the fact that there is at present no reliable, simple, and accurate apparatus for mapping out the central visual field (campimetry) or determining exactly the position and dimensions of central defects (scotometry). Most of the campimeters are merely dark screens or large blackboards placed at a distance from the patient of from three to seven meters. On these backgrounds or plane projections the fields, or defects in them, are plotted by various devices, such as inserting pins or markers. The procedure is laborious, slow, and cumbersome. The author has devised instead the following apparatus. It consists of a stationary black background corresponding to an area about 10 deg. to 15 deg. square, divided into degrees at the usual perimeter distance, *i.e.* 10 to 11 inches, which can be readily attached to the arc of the perimeter and moved along until the marker at its central zero point corresponds as closely as possible to the projection of the macula or of the blind spot, 15 deg. to the temporal side, as the case may be. To insure absolute fixation without fatigue or discomfort, one may have recourse to binocular stereoscopic fixation, a principle applied with success by Haitz. In this way the eye under examination is kept steady by its fellow; not only the central marker but the whole stereoscopic combination figure forms a sort of fixation frame, so that even in the presence of a central scotoma there is steady fixation. The patient is not conscious of the physiological exclusion of one eye from the visual act and function test. Abducting spheroprisms of about four diopters plus, corresponding to the test distance, serving as a stereoscope, may be attached to the head piece of the perimeter, a small central projection or partition serving to separate the fields of the two eyes. The test objects, not more than one to two millimeters square, must be held in the hand so as to be moved with the requisite rapidity and evenness, and with minute excursions. Rapid change of color should be possible, and the illumination should be constant. While these requirements can be met more or less with the usual color carriers, it seems that a single color test with concealed, artificial light source, adjustable diaphragm for accurately regulating the size of the visible test object, and rotating disk for rapidly bringing one color or another into view without change of position, would be a great improvement. Such a color carrier

would have the appearance of a diminutive electric ophthalmoscope (obviously without lenses); the disk being only about 25 mm. or 1 in. in diameter, and the miniature lamp of the smallest dimensions throwing light only through the small central aperture to be occupied by the colored glass or celluloid of the test objects. Instantaneous and intermittent exposure could be effected by suitable arrangement connected with the lamp contact, or by means of a small spring sliding shutter moving up and down in front of the diaphragm, as in the Fridenberg central color test. The necessary current could be supplied from a single pocket cell, or a cell in the handle of the color carrier.

3. **Eugenics.**—M. Solomon believes that the object of eugenics is not only to provide for a child a clean heredity but also to give it the best possible bringing up. For this reason he does not approve of separating euthenics from eugenics, as some are inclined to do, on the ground that euthenics stands for good environment and eugenics for good heredity. Although Karl Pearson has tried to read heredity, and heredity alone, into the definition of eugenics as laid down by Galton, the latter's definition of eugenics states that it is "the study of agencies under social control that may improve or impair the racial qualities of future generations either physically or mentally." He does not prevent environment from inclusion under the term eugenics. It is the science of being well born and well bred. Good heredity and good environment are opposite in their effects, but strengthen each other, and each is essential for the proper development of an individual. Either without the other is impotent.

4. **A New Decompression Operation.**—E. R. McGuire, after noting the imperfections of the ordinary decompression operations, states that the whole problem of decompression can be solved by an operation which makes the skull increase in size according to endocranial tension. Viewed from this standpoint, the usual operations are scarcely sufficient. At first the small circular opening was made; later a bone flap, and still later the subtemporal operation of Cushing. None of these makes the skull larger, but depends for its success on the development of a hernia. Hudson's operation consists in making a flap on one side posteriorly, sufficiently large to allow the hemisphere to be displaced backward. This makes the skull larger, and, by retaining the flap of bone with twisted wire sutures, it allows the skull to enlarge with relief of endocranial tension. The technique of the operation performed by the author differs from that of Hudson in that the bone flap includes both sides of the skull posteriorly, and in cases in which pressure seems to be below the tentorium, the dura is separated below the insertion of the tentorium posteriorly and opened below that point.

6. **The Monthly Incidence of Disease.**—H. A. Brown states that in the first six months of the year there are found excesses in the mortality from the exanthematous diseases and diseases of the respiratory tract, with suicide and violent deaths increasing in number during the spring and early summer. During the summer and fall there is an increase in the number of deaths from malaria, diseases of the digestive tract, and congenital debility, with a rapid increase again in November and December in the number dying from diseases of the respiratory tract.

4. **Cyanosis in Dementia Præcox.**—W. B. Cornell notes that a cutaneous cyanosis is found in a large majority of cases of dementia præcox, most frequently and intensely in the catatonic form, next in order in the hebephrenic form and then in the paranoid form. It is part of a generalized vasomotor disturbance consisting in a phlebostasis of unknown origin. Cyanosis is variable within large limits even in the same patient. Cyanosis offers a valuable diagnostic sign in differentiating dementia præcox from manic-depressive insanity, imbecility, hysteria, constitutional inferiority and occasionally the organic psychoses.

8. **The Various Carbohydrates in Infant Feeding.**—By H. D. Chapin. (See MEDICAL RECORD, Vol. 81, page 1160.)

13. **The Causes of Glycosuria.**—T. B. Futcher states that it must now be accepted as positively proved that not only the pancreas but also the adrenals (chromaffin system), thyroid, parathyroids, and pituitary have a very important influence on carbohydrate metabolism. Although lesions of the pancreas have been found in a considerable percentage of cases of diabetes, it is now clear that morbid changes in that organ will not explain all cases, even when alterations in the islands of Langerhans are also taken into account. The essential and primary disturbance may be in one or another of the ductless glands. There is observed a marked correlation of the internal secretions of the ductless glands. Thus the internal secretions of the adrenals (chromaffin system) and pancreas mutually retard the action of each other. The most recent theory concerning carbohydrate metabolism is that first advanced by Zuelzer and now supported by many physiologists. According to this view, one of the important functions of the adrenals is to "mobilize" or set free the carbohydrates in the liver and possibly in other storehouses also. Under normal conditions, however, this influence is counteracted or exactly balanced by the hormone contained in the internal secretion of the pancreas, and there occurs a constant normal flow of sugar from

the liver. When, however, the chromaffin system is for any reason overstimulated, as it may be through the sympathetic nervous system, there is an overproduction of the "accelerator" hormone of the adrenals; the "retarding" hormone of the internal secretion of the pancreas is more than counterbalanced, the glycogen in the liver is rapidly "mobilized" or set free and a hyperglycemia and glycosuria result. A similar result occurs in the cases of so-called pancreatic diabetes. Here the adrenal hormone may be normal in amount, but owing to the pancreatic disturbance the pancreatic hormone is absent or diminished and again the adrenal hormone is enabled to mobilize the glycogen of the liver. A somewhat analogous explanation may subsequently be found to explain the glycosurias in pituitary and thyroid diseases. The theory that hyperglycemia results from deficient consumption or oxidation of glucose in the tissues has fewer adherents than formerly. It may still be shown, however, that Cohnheim's theory is in part correct. At present the trend of opinion is in favor of the view that the hyperglycemia and glycosuria are dependent on overproduction of sugar in the liver.

**14. Vasostomy in Chronic Seminal Vesiculitis.**—R. H. Herbst has found that symptoms referred to the bladder and prostate are frequently relieved by vasostomy. In certain cases vasostomy has relieved symptoms ascribed to an enlarged prostate, just as did castration years ago. Vasostomy is especially indicated in cases in which one has to deal with either a partial or a complete occlusion of the ejaculatory ducts. This operation, Herbst says, gives a fairly high percentage of cures in a class of cases which must either be relegated to the incurable heap or be subjected to a far more dangerous and difficult surgical procedure.

**1. Pharmacotherapy of Pneumonia.**—Sir Almroth E. Wright, W. P. Morgan, L. Colebrook, and R. W. Dodgson report the results of their experiments with Morgenroth's drug, namely, ethylhydrocupreinhydrochlorate. These experiments bring out very clearly that, while the ordinary antiseptics are polytropic and expend their energy wastefully upon the blood fluids, we have in ethylhydrocupreinhydrochlorate a chemical agent which exerts its effect practically undiminished in serum. The experiments bring out that dilutions of 1 part of lysol in 500 parts of serum, dilutions of 1 part of creosote in 2,500 to 12,500 parts of serum, and dilutions of 1 part of guaiacol in 2,500 parts of serum fail to kill the pneumococcus; while dilutions of 1 part of lysol in 62,500 parts of water, dilutions of 1 part of creosote in 300,000 of water, and dilutions of 1 part of guaiacol in 1,500,000 of water, all kill the pneumococcus. They bring out further that dilutions of 1 part of ethylhydrocupreinhydrochlorate in 400,000 parts of serum kill the pneumococcus, and that dilutions of 1 in 800,000 inhibit the growth; and that the antiseptic values of the serum dilutions of the drug do not differ appreciably from the values obtained for watery solutions. Finally, they show that ethylhydrocupreinhydrochlorate exerts its bactericidal effect specifically upon the pneumococcus.

**2. Aural Vertigo.**—R. Lake states that chronic progressive middle-ear deafness and arteriosclerosis are the most frequent causes of aural vertigo, and fortunately one finds that a large amount of benefit can be derived from the use of drugs in these cases, though by no means all of them are capable of this relief. Operative interference is justified, and where it is used it should be uniformly successful. The author places small reliance on the rotary and caloric reactions. He also omits the so-called group in which increased labyrinthine pressure is said to exist. He is convinced that one is able to make one's diagnoses and one's prognoses in the class of case under consideration equally well without the employment of the above tests. With regard to increased intralabyrinthine pressure, although he has operated on at least twenty cases of labyrinthine vertigo where there had been no perforation into the labyrinth—fourteen of them where there had been no previous suppuration, and the rest where there had—he has only twice seen any fluid on opening the labyrinth. In these two cases there was a considerable amount of fluid; one of them also had an extremely large external semicircular canal, apparently four or five times greater than normal. But even then he is not prepared to say that these cases contained fluid under pressure. But it is rather difficult, indeed, to understand, from a purely mechanical point of view, how fluid can be retained under pressure in such a nonvascular bony cavity as the labyrinth.

**3. The Pneumothorax Treatment of Phthisis.**—C. Lillingston notes that in such a chronic and capricious disease as phthisis an estimation of the value of any form of treatment is worthless unless the number of patients treated is considerable, and the improvement effected has stood the test of time. His experience, therefore, with eighteen patients treated for periods ranging from six months to three and one-half years, is insufficient *per se* to build pretentious claims on, and he briefly touches on the following points. The disease was in the third stage and active, and the prognosis was very bad in every case. Yet the disease is either arrested or is undergoing arrest in thirteen. Five patients are either dead or dying; but the author believes that the treatment has prolonged their lives. More valuable are L. Spengler's results, for they have stood the test of a longer probation period. He has excluded all recent cases, confining himself to those in which a pneumothorax had been induced nine months to four years earlier. As evidence of arrest of disease he adopted the following conditions: Absence of pyrexia, cough, and expectoration; if the last be present, it must not contain tubercle bacilli. Fifteen patients fulfilled these conditions, and were also capable of a full day's work. In twelve of these the prognosis before the operation was almost hopeless, and in the remaining three it was very bad. Spengler considers that these results are a satisfactory answer to the objection that though a pneumothorax may cause temporary improvement, it does not often enough produce permanent results to warrant the risk of operation.

**5. Mucocele of Anterior Ethmoidal Cells.**—E. C. Alles states that mucocele of the ethmoidal cells alone, without any of the other sinuses being affected at the same time, is rare. Again, acute or subacute purulent sinusitis of the ethmoid is more frequent than are chronic degenerative inflammations. As to the causes of a mucocele there are two: it may be either caused by a chronic catarrhal inflammation of the mucous membrane lining the sinus, the ostium of which has become previously occluded; or it may be due to an occlusion of one of the ducts of the glands of the lining mucous membrane, and consequent dilatation of it. The contents of a mucocele consist of epithelial cells, blood corpuscles, and fluid containing mucin.

1. **Cardiolysis.**—Sir Robert M. Simon notes that in 1902 Brauer suggested that, in cases in which it was suspected that the free action of the heart was hampered by adhesions of the pericardium to parts outside it, it would benefit the patient to remove some of the bony and cartilaginous framework of the thorax. He supposed that the precordial part of the chest wall would thereby become more flexible and oppose less resistance to cardiac expansion. It is probable, however, that the relief to the heart thus given may lie less in the softening of the wall against which it beats than in the removal of tight and tough adhesions to the fixed points like the ribs, and that relief may be expected from the removal of these adhesions.

4. **The Parasites of Syphilis.**—By E. Jennings. (See MEDICAL RECORD, December 28, 1912, page 1171.)

5. **Certain Bodies Found in Syphilitic Lesions.**—By S. R. Moolgaokar. (See MEDICAL RECORD, December 28, 1912, page 1171.)

6. **Meteorological Conditions and Trypanosomes.**—A. Kinghorn and W. Yorke conclude that the developmental cycle of *Trypanosoma rhodesiense* in *Glossina morsitans* is to a marked degree influenced by the temperature to which the flies are subjected. High temperatures (75-85 deg. F.) favor the development of the parasite, while low temperatures (60-70 deg. F.) are unfavorable. The first portion of the developmental cycle can proceed at the lower temperatures, but for its completion the higher temperatures are essential. The parasites may persist in the fly at an incomplete stage of their development for at least sixty days under unfavorable climatic conditions. These observations afford an adequate explanation of the extremely long latent periods of trypanosomes in *Glossina* which have occasionally been observed by various workers. The relative humidity of the atmosphere has apparently no influence on the development of the trypanosome in *Glossina morsitans*.

7. **Salvarsan in Pernicious Anemia.**—E. Hobhouse reports the case of a woman who had been very anemic for more than a year and exceedingly ill in the previous summer, but who had improved under large doses of arsenic, and been fairly well during the winter. Her blood picture in October, 1911, showed no signs of pernicious anemia. On May 23 she was very ill with daily fever up to about 101 deg. F., was almost unable to sit up or take nourishment, and had loud hemic murmurs over the cardiac area; her color was the characteristic lemon yellow. A blood smear showed typical pernicious anemia. On May 31 salvarsan 0.3 gram was injected intramuscularly. Within three days benefit was apparent, though local pain was severe for about a week. In four days the murmurs had almost disappeared, and the patient was much stronger. Blood examination on June 4 showed a distinct improvement. On June 14 the improvement had continued, and the same dose was again injected; this was followed by a sharp reaction; the temperature rose to 101 deg. F. The patient looked exceedingly ill; the pallor and hemic murmurs returned, and she developed a large patch of dry pleurisy over the right back. This condition lasted a few days, when the fever slowly subsided and uninterrupted recovery set in.

*December 2 and 9*, 1912.

**The Falling Birthrate.**—Wolf states that for the past year the diminution of the German birthrate has been a theme of earnest discussion. The same status in France was long ago attributed to the two child system, which in turn is being replaced by the one child system. The result is that deaths surely outnumber births. It is therefore evident that a three child system should rectify the present alarming condition in that country. The alternative comprises the entrance into the country of alien blood. The relationship between falling birthrate and tendency to urban life is unmistakable, for it is in cities that the two and one child systems take their origin. In the midst of this state of affairs we find optimists who say that the decrease in births will run parallel to the decrease in deaths which is coming about as a result of improved education and sanitation. The urban tendency will also provoke a reaction towards rural life. Much may be done by averting the high summer nursling mortality of cities, etc. But the condition is so serious that it merits the most active interest on the part of all patriots. The author cites a recent work on the subject which he has had published in which he seeks a solution of the problem in a rationalization of the sexual life. He shows that many factors are hostile to an increased birthrate, while but few favor it. Statistics show that compulsory education is a sure provocation of race suicide. The illiterates of Russia and Roumania and the Balkan States contribute most heavily to the population. In many instances the influence of religion is similarly apparent. Roman Catholicism, although it has lost this power in France, is less compatible with race suicide than Protestantism in many localities outside of France; while the Protestants have more children than the atheists. Under the last term the author appears to group the socialists. The claim that prosperity means fewer children is, according to the author, a transposition of cause and effect. Fewer children bring about prosperity. An alarming tendency has been noted of late to race suicide in the rural districts of Prussia. The law will seem to be assured that countries with heavy and rising birthrates must come to repeople in time those with falling birthrate. In closing the author states that the Jewish birthrate is also falling off in countries where the general birthrate declines.

**Röntgen Rays in Gynecology.**—Cohn sums up an article as follows: The treatment of hemorrhages from the uterus with the rays is attended in many cases with good results and is to be thought of in all cases save those which depend on malignancy. The treatment is safe and may do away with much operative intervention. The untoward results of Röntgen castration are milder than those of operative castration; they never comprise psychoses and invalidism. The action of the rays upon hemorrhages is attributable to their influence upon the ovaries, which naturally bring about a determination of blood to the uterine mucosa. The myomatous uterus constitutes no exception. The rays are especially indicated in climacteric hemorrhages. That they have any direct action on uterine myomata has not been proven.

**Hypophysis Extract in Eclampsia.**—Krakauer tested the oxytocic action of this substance in a case of eclampsia in a young multipara of excellent muscular development. She had never been ill and the convulsions appeared without any warning. When first seen she was unconscious. It was only learned that she was not known to be pregnant over seven months and had a pendulous abdomen. Taken to the hospital, she received narcotics and chloro-

form, the spasmophilic state being extreme, along with wet packs. There were no signs of labor, and no fetal heart sounds were audible. Attempts were made to induce labor by rupturing the membranes and passing a soft catheter into the uterus. Dilatation was extremely slow and after 12 hours there had been but few pains and the os would only admit the finger tip. Hypophysis extract was now injected. The woman being still unconscious, the action of the pains was not very sensible, but in two hours the child was expelled dead. When consciousness was regained the woman, who had not expected her confinement for two or three months, could not realize what had happened. The child was mature, and it was impossible to fix the time of its death.

**Herpes Zoster and Varicella.**—Heim refers to von Bokay's series of cases in which varicella appeared to manifest itself as a zosteroid eruption. This series numbering nine cases extended over a period of twenty-one years. In one episode a patient with zoster appeared to have introduced varicella into a hospital, an adult developing the disease. Such cases may, of course, represent coincidences. The author, however, has seen a similar episode. A woman developed a typical thoracic zoster. Ten days later one of her children fell ill with chicken pox, and six days later another child who had not been exposed to the mother until four days later also developed the disease. These two incubation periods seem too brief for varicella and it is certain that the second child could not have contracted the disease from the first. The shortest interval under ordinary circumstances is placed at fourteen days, but freakish cases have reduced this to eight, so that the ten-day period for the first child and the twelve-day period for the second present no absolute difficulty if we decide that in both instances the virus proceeded from the mother's zoster. The mother had never had varicella. The zoster in these cases may show irregularity of distribution, and also come out in successive crops. It has been noted that zoster epidemics have occurred in communities simultaneously with chicken pox.

**Influence of Hormones on the Opsonic Index.**—Strubell has studied the staphylococcus index with especial reference to various drugs including some of the hormones (thyreoidin, pancreatin, adrenalin, etc.). This behavior may also be studied after the extirpation of some one of the ductless glands. He gave thyreoidin to rabbits and dogs and often noted a marked lowering of the index; but when the drug was given to normal human subjects in small doses the index improved. An injection of adrenalin in animals lowers the index. The same result followed extirpation of the adrenals. Pituitrin and parathyreoid in both lowered the index but several of the author's assistants who took pancreatin by the mouth showed a very considerable increase of the opsonic index. In the clinic we see in diabetes as a result of the failure of certain hormone action an exquisite lowering of the opsonic defence to the staphylococcus. This is not due to the increase of sugar in the blood. Others appear to have noted the action of pancreas substance in increasing the index. Our previous knowledge of drugs from this viewpoint is limited to the facts that iodine and bromine lower while arsenic increases the index.

**Gallbladder Peritonitis without Perforation.**—Wolff relates three cases of this sequence of which there appear to be two varieties according as the escaped bile is relatively normal or purulent. The gall bladder is distended and its contents seep through the more or less altered wall. A stone (or several) usually causes the obstruction which makes possible the conditions. On account of the great infrequency of these cases, one may be cited in detail: Three years after typhoid fever a patient was received at the clinic with symptoms of acute peritonitis. Diagnosis having been perforative appendicitis laparotomy was performed, whereupon over a liter of what appeared to be bile escaped. There was a moderate degree of parietal and visceral peritonitis. The appendix, although healthy, was extirpated and search was then made for a perforation in the biliary passages. The gall bladder was distended, the walls appeared normal, no stones were to be found within and the serous coat was not implicated in the peritonitis. Although no perforation could be found in the bile passages a drain was placed beside them. The wound healed, however, without any escape of bile and without other incident. The second case was similar to the first. In the third case the patient died of postoperative paralysis of the intestine. Distention of the gall bladder was shown to have been due to calculi. A most careful research failed to show perforation anywhere including the stomach and intestine.

*December* 3, 1912.

**Total Gangrene of the Breast in Puerperal Sepsis.**—Bamberger cites figures to show the infrequency of gangrene in the puerperium as a part of the picture of sepsis. Of 80 cases collated recently, representing all upon record, 58 were seated in the lower extremities. There was one case of gangrene of the breast (nipple), sacrum, external genitals, and heels. In another of typical puerperal scarlatina that was circumscribed gangrene of the breast. Finally a case of puerperal mastitis which had become chronic, terminated in gangrene. In the author's case, seen in consultation, there was severe sepsis, which was called puerperal only because it appeared after delivery. There were no antecedents pointing to puerperal infection. The symptoms were limited to high temperature and left mastitis. On account of the great swelling and pain an incision was made but no pus escaped. When the consultant arrived the patient in addition to high temperature showed dyspnea. Heart appeared to be intact however. Nothing abnormal about the genitals save slight tenderness over left parametrium. The entire breast was blue-black, without fluctuation. The infant had not been placed on the breast as even so early in the puerperium the patient had been feverish. The breast was at once amputated although with not much hope of saving life. The gangrene was arrested and the sepsis proceeded to a fatal termination. No autopsy is mentioned. The assumption had naturally been that embolism developed in the mammary arteries in connection with occult sepsis from absorption through open uterine sinuses of some toxic-infectious material. Labor had been easy, spontaneous.

**Dysbasia Angiosclerotica.**—Pick has treated a number of cases of intermittent limp associated with cold feet. In all there were thirteen patients whom he was able to control for at least four weeks. Many observations of this affection are defective because the patients were seen but once or twice. The cases were typical, occurring in men past middle life with the usual causal factors of nicotinism, syphilis, gout, lead, cold, etc., and more or less collateral evidence of arteriosclerosis. Treatment consisted in the exhibition of iodine vapor, which does not irritate the stomach or cause iodism. The benefit from this resource appears to be prompt. The circulation of the legs is unburdened by respiration under lowered pressure. During this treatment the ankle pulse reappeared. There was as a whole much amelioration of symptoms, but to speak of permanent benefit in such a chronic affection would be premature. One almost certain result of such treatment is to prevent angiosclerotic gangrene.

**Self-cure of Appendicitis.**—Deppe in the course of laparotomy for various pelvic disorders has placed on record six cases of self-healed appendicitis. His operations

were undertaken for uteroovarian conditions, in which the appendix is often found diseased and is hence removed. In some of his six patients there was no history pointing to appendicitis. In two hardly any appendix remained (so-called self-amputation); in two others it was adherent to the abdominal or pelvic wall but no longer itself inflamed, having become sealed up by the peritoneal inflammation around it. The remaining two cases are peculiar in that absolutely no trace of an appendix could be found. There were scars in the cecum at the point of insertion. The only explanation is that a gangrenous appendix had sloughed and had slowly been absorbed in the peritoneal cavity. The author holds that pregnancy-contributes somewhat to the self-healing of appendicitis.

*November 28, and December 3, 1912.*

**Treatment of Psoriasis.**—Jungmann refers to the necessity for dietetic supervision but this seems to differ much with the physician's bias. It may be that any diet which will modify the metabolism possesses some element of benefit. A meat eater might improve on a vegetarian diet, an obese patient on a reduction cure, a gouty subject on an antilithic regimen, etc. In the same manner a complete Carlsbad or Kissingen cure may act by modifying the metabolism. Physicotherapy as a rule is not especially well tolerated and some forms as the *x*-ray are often injurious. Arsenic, the most useful drug, demands careful study to get good results. There is danger of intoxication and also of abstinence symptoms after prolonged use. Next in order come iodides and thyroidin, which may be given in combination with arsenic. The number of local remedies known to be able to modify favorably the lesions is now very large. Some of the best are able to cause constitutional symptoms when used too long or too copiously, and also if not watched may cause severe local reactions. From this viewpoint tar is the least injurious and is also cheap, having no drawback save the odor. Another dependable remedy and one always useful when not too many lesions are present is white precipitate. The stronger, more irritating, and disfiguring substances like chrysarobin and pyrogallol should be used in selected cases—in circumscribed discoid forms where it is desirable to secure relatively prompt temporary results. The *x*-ray has about the same range, in that it may exert power temporarily over certain lesions but cannot be used universally month in and out. The various other forms of radiation as the Finsen light, uviol lamp, quarz lamp, etc., have power over the lesions, but are not adapted to general use.

**How Long Does Typhoid Fever Remain Infectious?** Schumacher states that he does not refer under this heading to the carrier problem, else the answer might be "throughout the carrier's life." The cases he considers give off bacilli for a longer or shorter period after which they become sterile. During the active period some measures must be taken to protect the public by suitable disinfection, so that an arbitrary interval is usually adopted. The author has followed up cases presumably sterile after the final official examination and has in certain cases seen bacilli reappear in the urine and persist therein for a number of weeks. He would keep typhoid convalescents segregated and controlled for at least six weeks after deverfescence.

**Bone Formation in a Cicatrix.**—Kumaris relates a case of this type. A vigorous young man after a fall upon the right knee had a series of abscesses in the thigh—upper, outer aspect. When first seen by the author one extensive scar remained as evidence of the process itself and of several operations performed from time to time. The painful, sensitive character of the scar suggested a coming recrudescence of the process. The tissues were therefore laid open and bone was found in the center of the cicatricial tissue. This fragment, 4 cm. long and of finger thickness, was not a sequestrum. There appeared to be no evidence of misplaced periosteum or of possible migration of a bit of live bone during operation. A histological study seemed to show that a true metaplasia of bone had occurred in normal scar tissue.

**Plague Pneumonia in Brazil.**—Rau states that twelve years ago the bubonic plague was unknown in the city of Santa Maria, in Southern Brazil. First introduced from India by way of Rio Janeiro, it has for four years past become epidemic. Two cases first occurred in one house, one of which ended fatally. No new cases were reported for some weeks, when other sporadic instances occurred in other quarters of the town, and became numerous but without epidemic features. In most of the affected houses rats also died of the disease in large numbers. All the human cases showed typical bubonic plague, with mortality of fifty per cent. Almost over night the situation now altered, and at the height of the winter season. In an unsanitary bakery a boy fell ill of severe pneumonia, dying in three days of pulmonary edema. A few days later the two women who had cared for the boy fell ill and died of the same malady. Numerous near relatives of the women then sickened and died. A priest was also a victim. The type of disease was so severe that one death occurred within 24 hours. There were in all eighteen victims, with mortality of 100 per cent. The symptoms were of severest pneumonia, causing death in from two to five days of edema of the lungs. No patient showed any buboes save one who was seen to have swollen cervical lymphnodes. Yersin's plague serum had no influence over the disease. The cadavers decomposed rapidly. In the house which sheltered the first victims two hundred dead rats were found. The transmission appeared to be effected through the saliva and sputum. In limiting the spread of the disease strict quarantine and formalin disinfection were employed. Exposed persons were isolated for ten days. Prophylactic injections of Yersin serum were used in certain cases and a temporary plague hospital was established. The public was ordered to destroy rats and mice and use insect powder. The evidence showed that there is no room for a dualistic hypothesis, as the pneumonic form was derived directly from the bubonic form.

**Anaphrodisiacs.**—Frank considers this subject in connection with a new synthetic which contains bromine and borneol. The number of drugs having anaphrodisiac tendencies is very large and they have been arranged in five groups, viz., 1. Adynamics. Under this head are groupted all so-called antispasmodics and anodynes which lessen the excitability of the nervous system. Here belong bromides, camphor, heroin, morphine, atropine, hyoscyamine, physostigmine, cannabis indica, conium, lupulin, and numerous others which possess slight activity. 2. Hypnotics. All the members of this group, notably veronal, sulphonal, etc. 3. Antipyretics and sedatives. Here belong many coal tar derivatives as well as salicylic acid. 4, 5. Here belong, in theory at least, all substances which alter blood pressures and chest secretion. Bürgi's principle of potentizing one drug with a small quantity of another, a synergist, may be employed in prescribing anaphrodisiacs. Von Noorden, testing Bürgi's theories, found that a small quantity of codeine would activate veronal, as would also phenacetin. Naturally this principle should be of great help in building up synthetics, and one of the newest veronal modifications is a synthetic composed chiefly of this substance or at least its urethane group with small quantities of the active groups of codeine and phenacetin. In like manner an anaphrodisiac may be formed by combining bromine with borneol. A desirable preparation of this sort is especially indicated to control sexual excitement with perverse sexual inclinations.

# Insurance Medicine.

## SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

### LIFE INSURANCE COMPANIES.

Strictly speaking, insurance of all kinds is mutual as the claims are payable out of the premiums paid by the insured. This has been true since the earliest and simplest forms and is illustrated in benefits paid by the middle-age guilds and still earlier in the methods practised by the traders of ancient Rome. Level premium life insurance was introduced by the "Society for the Equitable Assurance of Lives," also a purely mutual affair now known as the "Old Equitable" of London. This company was established in 1762 and encountered much distrust of the newly devised method of level premium insurance, men preferring the older and known associations, even though their settlements were far from satisfactory and their careers doubtful. The "Old Equitable" went on, nevertheless, and led the way towards charging adequate premiums and maintaining sufficient reserves, and as a result of this course survives to this day.

Insurance companies, according to the general acceptance of the term, however, are classified as mutual, stock, mixed, industrial, and assessment.

Mutual.—A mutual life insurance company is one in which there is no capital stock, all of the gains and savings belonging and going to the policyholders. The policyholders also elect the trustees and in this way control the management of the company. Companies formed on this plan are able to insure their policyholders at net cost and it is, perhaps, for this reason that they are so favored and successful and that they carry very considerably over half the insurance in force.

Stock.—A stock company is one having capital stock. The shareholders elect the trustees and control the company. Moreover, all the profits inure to the benefit of the shareholders. By comparing the mutual and purely stock companies it is seen that the ultimate cost of insurance ought to be less in the mutual than in the stock companies, for it is possible on the mutual plan only to provide the policyholder with protection at net cost.

Mixed.—While the so-called mixed companies have a combination of the features of both stock and mutual companies, they are really mutual in essential particulars. They have a capital stock owned by the shareholders who elect the trustees and so control the management. The shareholders are only entitled to a small percentage of the profits and the balance goes to the benefit of the policyholders. This is a common and often successful form of life insurance company.

Industrial.—This form of insurance was established in England in 1854 by the issuance of industrial policies by the "Prudential Assurance Company of London," in addition to the writing of ordinary insurance. In 1875 the "Prudential Insurance Company of America" was started for the purpose of writing industrial and ordinary insurance. The essential difference between industrial and ordinary insurance is in the method of premium payments, the premiums in the former being payable weekly and collected by agents at the houses of the insured, whereas in the latter the premiums are payable quarterly, semi-annually, or annually at the offices of the companies. Naturally, the premiums for industrial insurance are high on the same principle that coal costs more when bought by the bucket. The company itself may be mutual, stock, or mixed.

Assessment or Fraternal.—An assessment company is one in which there is an association of individuals, each of whom agrees to pay an assessment on the death of a member, or at regular intervals in order to keep a mortuary fund up to a certain sum. Thousands of associations on the assessment plan, as applied to life insurance, were organized in Great Britain in the eighteenth century, a large proportion of which succumbed. The origin of fraternal beneficiary societies in America dates back to 1868 when John Upchurch, a mechanic, conceived the idea of founding the "Ancient Order of United Workmen." Many of these societies have been the means of affording insurance to men who were unable to met the expense of policies in the regular level premium companies. On the other hand, a large number of them have collapsed and these misfortunes have brought hardship to the families of members of old standing. It is not difficult to discover the reason for the failure of some of these associations.

In the early days of these fraternal or assessment societies when most of the members are young, the mortality among the policyholders is naturally very light. Consequently only a small part of their premiums are required to pay the death claims of the few policyholders of recent or older standing. As time goes on, however, each group of policyholders has to supply the means of paying the claims of their predecessors and must look for the payment of their own claims to the contributions of their successors. In other words, there are no adequate reserves, so the life of the society depends on the infusion of "new blood," and, therefore, possesses no element of stability, especially so as many of the younger and healthy members withdraw and seek insurance elsewhere rather than pay for the excessive premiums due to the gradually increasing death rate among the older members. A number of the societies are undergoing a process of readjustment and are now operated by charging the current cost of insurance at the various ages and at the same time attempting to provide for an emergency fund to take care of any deficiencies that may have been created in the past and to relieve the cost at the older ages.

The chief difference between assessment companies and those previously described is that any one of the latter, properly managed, is conducted on methods which provide reserves so adequate that it can terminate its career, as far as new business is concerned, at any time and still have sufficient funds to carry out all of its outstanding contracts.

---

**Some Experiences in Medical Selection for Life Insurance.**—Dr. S. T. McDermith of Denver has recorded some of his experiences in medical selection for life insurance, which he gathered during the past fifteen years in the capacity of medical director of a fraternal insurance order. The gist of this paper is to point out and emphasize how much more skilled in the difficult art of weeding out unsatisfactory applications, the medical examiner of the present is than the examiner was at the time that Dr. McDermith commenced his duties as the medical director of a life insurance organization.—*Denver Medical Times.*

# Book Reviews.

Ein Weiterer Beitrag zur Glaukom-Frage. By Dr. W. Wagner (Odessa), Berlin. Price 1.50 M. Berlin: Verlag von S. Karger, 1912.

The author describes glaucoma as he himself experienced it. The glaucoma occurring in his left eye, was apparently complicated by a retrobulbar neuritis 30 years after the first attack and the eye became blind. An acute attack of glaucoma occurred in the right eye 31 years after glaucoma began in the left eye. The author goes on to discuss the theories of glaucoma and the operative treatment. The brochure, which comprises 47 pages of text, forms an interesting contribution to the literature on glaucoma.

Practice of Medicine. A Manual for Students and Practitioners. By Hughes Dayton, M.D., Associate Attending Physician, New York Hospital; formerly Instructor in Physical Diagnosis, Cornell University Medical School, New York. Second Edition, revised and enlarged. Price $1 net. New York and Philadelphia: Lea & Febiger.

This is probably the smallest "Practice of Medicine" in the market. This branch of the medical curriculum does not lend itself to "compend" treatment as well as some other subjects do. The volume may be of service as a guide to the medical student in his perusal of larger and standard works; but the very scanty consideration of the treatment of disease renders it of little use to the practitioner.

On the Oxidations and Cleavages of Glucose. Yeast Glucose, a New Glucolytic Ferment. By Victor Birckner, University of California Publications in Physiology. Vol. 4, No. 16. Berkeley: University of California Press, 1912. Price 75 cents.

In this very careful study the author gives first a systematic review of recent advances in the knowledge of glucose oxidations and cleavages, and then describes the isolation of a new ferment from beer yeast which has peculiar and distinctive properties.

Der Kohlehydratstoffwechsel und die innere Sekretion. Für Forscher und Praktiker. Von Dr. Paul Höckendorf, Spezialarzt für Stoffwechselkrankheiten, Berlin-Charlottenburg. Price, marks 2.40. Berlin: August Hirschwald, 1912.

The author discusses the conditions under which glycogen is stored in the liver and the mechanism which controls the periodic liberation of certain amounts of this substance, as well as the formation of sugar from fat and proteid. These considerations lead to an interesting presentation of the probable derangements underlying the condition of diabetes.

The Chemic Problem in Nutrition. (Magnesium Infiltration). A Sketch of the Causative Factors in Disorders of Nutrition as Related to Diseases of the Nervous System. By John Aulde, M.D. Formerly Assistant Physician, Out-Patient Department, Jefferson Medical College Hospital; Demonstrator of Physical Diagnosis and Clinical Medicine, Medicochirurgical College, etc. Illustrated with four plates. Price $3.00. Philadelphia: John Aulde, M.D., 1912.

While the author modestly terms the present contribution "a sketch" it is in reality a closely printed volume of over four hundred pages, and covers the etiology and treatment of most of the diseases known to medical men, as well as some other conditions, such as "laziness," not usually considered in books devoted to the ills of the flesh. The problems both of causation and therapy, are however, much simplified by the author's view that in most cases it is an abnormal reaction of the body fluids and tissues with consequent derangement of the chemical balance of its inorganic constituents that is at fault, and that the conditions necessary for health can readily be restored by a few therapeutic measures which are described in detail. The introductory chapters contain elaborate chemical and physiological discussions which are used as a basis for the conclusion that a reversal of the body's reaction from alkaline to acid leads to a disturbance of the normal relationship between the calcium and magnesium content of the tissues. As a result the elimination of calcium is unduly favored, while magnesium accumulates, and a highly injurious state of "magnesium infiltration" supervenes, carrying in its train the potentiality for the development of almost any disorder. A chapter on "The Food Problem" with dietary tables shows how easily quite unsuspected amounts of magnesium may be ingested, with ensuing derangements of digestion, of assimilation, and of the nervous system. The treatment of appendicitis, for example, accordingly is summarized as follows: "1. Neutralize acid excess by means of alkaline-saline medication; 2. Counteract the tendency to clotting in the lymph channels and glands by the employment of an alterative, calcium sulphide; 3. Avoid Epsom salts (magnesium sulphate), and promote magnesium dissociation by the employment of its known antidote, calcium salts; 4. The presence of bacterial flora in excess in the intestine should be controlled by remedies which act through the medium of the nervous system, in the form of colloids, or by symbiosis." Practically the same treatment is recommended for pleurisy, pneumonia, pericarditis, peritonitis, meningitis, arthritis, earache, headache, neuralgia, tonsillitis, neuritis, goiter, mastitis, skin diseases, etc. The book is also provided with a very extensive index.

Kohlenhydratkuren bei Diabetes. Von Dr. Georg Rosenfeld in Breslau. Sommlung zwangloser Abhandlungen aus dem gebiete der Verdauungs und Stoffwechsel-Krankheiten, herausgegeben von Dr. A. Albu in Berlin. IV Band, Heft 3. Price, marks 1.70. Halle A. S.: Carl Marhold, 1912.

Rosenfeld discusses all the carbohydrates that can be made use of in the treatment of diabetes, giving for each "cure" a résumé of its method of application and an opinion in regard to its value. The greatest amount of space is devoted to the potato cure, which he deems of doubtful benefit, and to the oatmeal cure which he considers highly serviceable in properly selected cases.

Autointoxication and Disintoxication. An Account of a New Fasting Treatment in Diabetes and Other Chronic Diseases. By Dr. G. Guelpa (Paris). Translated by F. S. Arnold, B.A., M.B., B.Ch. (Oxon.). With an introduction by the translator and a chapter on the use of the method in the treatment of morphine addiction by Oscar Jennings, M.D. (Paris). Price $1.25. New York: Rebman Company.

Dr. Guelpa founds his system of "disintoxication" on two elements of treatment of universally recognized value, viz., abstinence from food and purgation. This he carries out with great thoroughness, and claims that in this way remarkably beneficial results are obtained in a wide variety of conditions, notably diabetes, rheumatism, albuminuria, and gout. The régime consists in taking each day for two, three, or four days an entire bottle of well-known laxative water, abstaining from all food during this time, and drinking as freely as desired of water, weak tea without milk, toast and water, fruit infusion, etc. Evidently recognizing the *a priori* nature of much of the reasoning—by means of which he seeks to explain the effects of this treatment (such for example as the statement, unsupported by evidence, that the sensation of hunger is caused by the presence in the body of more or less toxic effete matters), the author admits that its justification may best be found in the results obtained when it is applied, and to this end many case histories are cited. In all of these the effect was excellent, and Dr. Jennings closes the volume with a chapter in which the method is lauded highly in the treatment of morphinism.

A Treatise on Diseases of the Hair. By George Thomas Jackson, M.D., Professor of Dermatology in the College of Physicians and Surgeons, Medical Department of Columbia University; and Charles Wood McMurtry, M.D., Instructor of Dermatology in the College of Physicians and Surgeons, Medical Department of Columbia University. Illustrated with 109 Engravings and 10 Colored Plates. Price $3.75. Philadelphia and New York: Lea & Febiger, 1912.

This is the first authoritative work on the diseases of the hair that has appeared in the English language. It is well adapted for the use of the general practitioner and may be recommended to the latter as a volume which will greatly assist him in the treatment of a large group of cases that regularly present themselves. The authors have drawn freely from their own ample experience and from the exhaustive treatises of Sabouraud and Darier. The first division of the work discusses the anatomy, physiology, and hygiene of the hair. In the second division are described the essential diseases of the hair. The third section deals with the inflammatory diseases of the hair follicle. The parasitic diseases of the hair are described in the next section, while the last division of the work discusses those diseases of the hair secondary to diseases of the skin. The volume contains a large number of helpful illustrations, some of which are colored. There can be little doubt that this book fills a distinct gap in English medical literature.

## THE PRACTITIONERS' SOCIETY OF NEW YORK.

*250th Regular Meeting, Held November 1, 1912.*

Dr. John W. Brannan, President, in the Chair.

**Mental Tests.**—Dr. Charles L. Dana read this paper (see page 1).

Dr. Starr said he wished to express his gratitude to Dr. Dana for having gotten together these tests and put them into form in which they gave us a definite method to follow. He had used these different tests but they had not been in definite form. That was the great advantage of the Binet method which he had used in private work but found too long for clinic work. One of its advantages lay in the fact that you could demonstrate to a family that a member of the family was really below a certain rating of intelligence when the members of the family told you of the extreme mental ability of the child or older patient. He had found these tests also of a great deal of service, especially in the last five or six months, in contrasting the mental progress, as he could tell whether the child had improved or not from one examination to another. He was very glad to have these tests of Dr. Dana's and hoped that Dr. Dana would print them in definite form so that we could have them for use.

He agreed with Dr. Dana that a majority of psychasthenics showed a defective grade of high mentality and thought the psychasthenic type was a definite type. He had a word to say about the association tests of Jung, which he did not think had given him any definite knowledge about mental processes, nor had he seen any benefit from them in a therapeutic way. He thought that in the hands of certain men definite results had been obtained in gaining insight for control, but he did not believe that the results had been on account of the method but because of the personality of the physician. That was, he thought, the secret of their success. He considered psychoanalysis a new word for old methods. He believed the rest cure of Dr. Weir Mitchell was successful because it was carried out by Weir Mitchell, and the benefit was gotten from Dr. Mitchell personally. His personal influence tended to put that patient on a new mental plane different from his old and ordinary one. That was why the rest cure had done good in Dr. Mitchell's hands, but had not been as successful in the hands of others. He said he had no faith in the interpretations of dreams.

Dr. Horace Frink said that it was unnecessary for him to state that he believed in psychoanalysis, though, as Dr. Starr remarked, the personal influence of the physician was doubtless an important factor in the treatment. This, however, did not diminish the importance of the analysis itself, nor did it adequately explain the therapeutic results that were obtained. The diagnostic value of the association test was not great, yet in conditions of dementia præcox or manic depression, epilepsy or hysteria, etc., the results of an association test, considered with the other clinical findings, were occasionally of some aid in making a differential diagnosis. The chief use of the test was not in making diagnoses or determining intellectual levels, but in investigations as to the state and content of the emotional life. Thus in some cases the form of the test as a whole was significant. For instance, certain individuals reacted by defining most of the stimulus words. Such a test, occurring in a person of average intelligence, gave evidence of a feeling of inferiority—the test person was afraid of being considered stupid, he was not satisfied with the impression he was making and was therefore impelled to affect mannerisms, high sounding phrases, and a behavior not natural to him in order to raise himself in the estimation of his friends and acquaintances. A second type was characterized by emotional exaggeration. The test person gave frequent reactions such as the following:

Work—Detestable.
Hat—Enchanting.
Music—Sublime.
Noise—Maddening.

From a test of this type, showing a strong emotional accentuation of personal judgment, one inferred that the test person was compensating for an emotional void. That is, the individual's life was empty, so to speak, and failed to offer sufficient occasion for emotional discharge. To compensate for this want the person unconsciously put more feeling than was demanded into all activities which offered any opportunity for effective expression. One would expect this type of test in a married woman in the forties who had no children, little love for her husband, no particular interests, and nothing to do. An examination of the individual reactions of the test gave information as to the main emotional trends of "complexes" which dominated the test person's life and furnished the motive power of his neurosis. It was common knowledge that, in certain criminal cases, the representatives of the law sought to determine the guilt or innocence of the suspected person by suddenly confronting him with a reproduction of the scene of the crime. If he behaved with perfect calmness and appeared to feel no particular emotion the assumption of innocence was favored. If he betrayed excitement, fear, became confused, spoke incoherently, or was unable to speak at all, he might be considered guilty. If we could study the reactions of our patients by confronting them with various reproductions of reality it was obvious that much of interest might be learned. This could not be done, however, but in the association test we had a very good substitute for such a method of procedure. The words of the test corresponded to a part of some reality, and the behavior of the test person toward each word was an index of what his behavior would be toward the reality itself. If a person was under strong emotion he might have considerable difficulty in speaking, might for a short time be unable to speak at all, might speak incoherently, and, later, might have little or no recollection of what he had said. In a quite similar way the test person would react to those words of the test which connected with emotionally accentuated complexes. To such words his reaction would be delayed, or fail entirely. Or, it might be superficial or senseless, or, on going over the test a second time he might not be able to recall correctly what his response had been. By this and other signs the physician was able to determine which words of the test connected with faulty complexes. In some cases one needed only to put these "complex indicators" together to get a very definite idea of the main pathogenic trends of the patient's life. But usually it was necessary to require the patient to associate the words of the test before one could be sure to what themes the different reactions referred.

In going over the results of the test in this way it would usually be found that most of the reactions could be grouped as referring to one or another of four or five themes, such as death, religion, a loved person, etc. We would then be able to say that the person under examination had a "death complex," an "erotic complex," a "separation complex," or whatever the case might be. In this way the test showed what complexes were at work in the patient. The task then remained of discovering the content of those complexes and its relations to the symptoms and of bringing the whole into the patient's consciousness. Upon this the most difficult and lengthy part of psychoanalytic work, the therapeutic result depended. Here the test was of little assistance and one depended more upon "free association," the analysis of dreams, and similar measures. The work of Rosanoff on association was interesting but could not be looked upon as bearing upon the question of the value of the association as an analytic measure, and, in the speaker's opinion, neither supported nor disproved anything Jung had said.

Dr. Brannan asked whether the tests were practical or easily enough done for use in schools, in the work of Dr. Maxwell, etc., and if the methods had helped in curing Dr. Dana's patient with epilepsy of four years' duration which was found to be of hysterical character.

Dr. Dana, replying to Dr. Brannan, said that the purpose of these tests was just what Dr. Brannan suggested. The backward children in the schools could be sent to clinics and tested. There were places in New York where this was done. There was a strong movement to try to segregate the 2,000 or 3,000 children in the schools, who were defective. It was claimed that we should not spend our money on them and take up time from teaching healthy children, but that the teaching of retarded children should be in special institutions. The same type of cases were found in the courts and in the clinics; they grew up and became a menace and the State had to take care of them, so it seemed to him right for physicians and public-spirited people to make themselves especially familiar with the problem. The case of epilepsy referred to was only a recent one, but these cases did get well sometimes. The tests did help the diagnosis and treatment.

**Preventive Inoculations of Typhoid Fever.**—Dr. John W. Brannan read this paper (see page 10).

Dr. Meara said his experience had been limited. He had vaccinated himself and a few patients. There had been very slight reactions. The number of patients he had vaccinated had been too small to draw any conclusions from. He asked if in children there was any contraindication to inoculation.

Dr. Biggs said he considered it very unfortunate that the word vaccination had been used in this connection. There

had developed lately considerable opposition to vaccination against smallpox, and this was especially so in the West. It was unfortunate to have anything else associated with the word in the popular mind.

Dr. Park said in answer to a question that the "sensitized" vaccine had been tried on animals but had not given as marked an immunity. Most of the experiments, however, had been made with sensitized dead bacilli. There had not been enough cases of inoculation with the sensitized live bacilli done as yet to show anything conclusive. There was nothing to show, however, that the antibodies produced after injection with living gave any different results from those injected with the dead bacilli. Appreciable agglutinins did not always develop after an inoculation. This did not necessarily indicate that other antibodies had not been formed." He had just been doing some tests with diphtheria. Different patients developed after immunization different kinds of antibodies. This was true for many forms of immunity. They had found in the Health Department that smallpox immunity in exceptional cases might only last nine months, and so they vaccinated employees every year. Recently typhoid infection entered a community which had been immunized ten months ago. Three out of seventy-five immunized persons developed typhoid fever. A doctor and an orderly who had not been immunized developed the disease. An interesting case was furnished by one of the young women in the research laboratory by accident. She was transferring typhoid culture through a pipette from which the cotton had been left out and she sucked some of the bacilli into her mouth. They had tried to clean and sterilize her mouth and gave her vaccine, but she had the disease. The question came up as to immunizing her. They had tried to do so by vaccination but were unable to prevent the disease. Dr. Park said there was no reason, in his opinion, for not inoculating children.

He said he did not think there was anything in the suggestion that the periods between the inoculations should correspond to the ordinary duration of the disease. The antibodies, once developed, should last for months. It was only when antibodies obtained from an animal of another species are introduced that they were quickly eliminated. At the Health Department laboratories the organisms were killed by exposure to a temperature of 60° C. for one-half hour after sterilization. Carbolic acid was added to .25 per cent. The vaccines were standardized by the "Wright" method. Attempts had been made to treat typhoid carriers by vaccination but they refused to continue the treatment. Meader of Syracuse had carried out this treatment in three cases for long periods of time. Two had recovered. He had kept the inoculations up for about one year in these cases before they recovered. The one who had not recovered did not produce abundant antibodies.

Dr. Smith asked if attempts had been made to free typhoid carriers by inoculation.

Dr. Starr asked if the reaction to inoculation was greater in children under twelve or fourteen than it was in adults.

Dr. Brannan said that the surgeons of the English Army had found that vaccination of typhoid carriers caused only temporary disappearance of the bacilli. He said that he had had no experience with children but that he would be inclined to give them smaller doses. He believed that ultimately smaller doses would be given to adults and that they would be extended over a longer period of time. One of the speakers at the Congress on Hygiene at Washington thought that we should try to spread the inoculations over a time corresponding to the duration of the disease. He found that the word vaccination caused considerable apprehension. The nurses thought that their arms were going to be scratched and made sore as in vaccination against smallpox. When they learned that the inoculation consisted of a small hypodermic injection there was no further trouble.

He considered it very important to use only vaccine of standard strength, such as that prepared by the Board of Health. He knew of several instances in which perfectly competent bacteriologists had used vaccines prepared by themselves and the reactions were very severe. Dr. Gibson had spoken of the importance of having house staffs treated. It had been the intention to have this done in all the hospitals, but there was great reluctance among the staff about accepting it. At Gouverneur, Harlem, and Fordham all of the men had been inoculated and some had marked reactions. At Bellevue not more than half of the staff had been inoculated to date. At all of the hospitals all sorts of excuses were put forward, such as ambulance duty, vacation, etc., but as a rule they did not prevail. A physician at Hartford told him that at the Hartford Hospital the staff as a body refused inoculation.

SECTION ON PEDIATRICS.

*Stated Meeting, Held November* 14, 1912.

Dr. William Shannon in the Chair.

**Relation to and Influence Upon Respiration, During Childhood, of Normal and Abnormal Dental Arches.**—Dr. Arthur Zentler presented this communication. He stated that the question as to whether adenoid growths were the cause or the results of constricted dental arches, though much debated, had not been satisfactorily solved. It had been shown that proper breathing was interfered with wherever adenoids were present and that constricted dental arches were almost always an accompaniment of this condition. A normally developed set of dental arches preincluded a normally developed maxilla and mandible. Normally developed mandible and maxilla were only found where teeth were existent and were in proper occlusion and where occlusion existed there normally developed dental arches would be found, notwithstanding the proportion of the width of the arch to the size of the teeth. The size of the teeth was not infrequently not in proportion with the stature of the individual, nor with the shape or the size of the head. In proportion as the occlusion was more or less perfect the dental arches would be more or less well developed and the more nearly normally developed the dental arches were the less would the nasal septum deviate and the larger would be the nares and, in consequence, the nasal breathing would be better. The nasal septum might be straightened and the nares also made proportionately larger either by a rapid or a slow process of widening of the dental arches. In deciding which of the two factors should be selected many things should be considered. Whether the widening was the result of space produced between the two maxillary halves in opening the maxillary suture, or whether it was the result of an expansion of such portions of the palatal bone as were less resistent between other teeth was not definitely established, but it appeared that the latter was the case. It was certain that no ill effects resulted from either process and at once obvious that the nasal respiratory passages must be improved as a result of this operation. If adenoids were not removed at all or only after the sixth year constricted dental arches were almost invariably found. Wherever adenoids existed in infancy and were removed at an early age one was almost sure to find well-developed dental arches. However, it was possible to find constricted dental arches where there were no adenoids and it could not be said that because this child had no adenoids it could breathe properly. The same factors which influenced the development of the dental arches also influenced the development of the muscle controlling the upper lip. The upper lip would be found drawn up and held there, and closing the lips was not a natural process and was not done during sleep except by applying special bandages. The muscles of the cheek in such cases acted as compressors and did not allow the maxilla and mandible to develop laterally. At the same time keeping the mouth open changed the normal position of the tongue when in repose, so that instead of resting flat against the roof of the mouth and thereby contributing to the lateral development of the maxillary halves, dropped to the floor of the mouth, assuming an elongated shape and contributing to the forward moving of the lower teeth, thus augmenting the contraction of the lower arch already brought about by the muscles of the cheeks and lower lip The open mouth habit would not disappear after the removal of nasal obstructions until the anatomical deformity was corrected. The efficient application of constant force by the use of adequate apparatus, which did not hurt if properly constructed and adjusted, would spread the dental arches to their normal shape until the teeth had come into normal occlusion, the lips closed normally and the child breathed normally through the nose. Barring general conditions which might be contraindicative it was never too early to remove adenoids and for the same reason it was never too early to bring the dental arches into shape. The earlier the teeth were brought into proper occlusion the easier and more permanently would they be kept so. The need of retaining the teeth in their new position was in direct proportion with the early age during which they were moved. If the early teeth were in faulty occlusion the permanent teeth would also be in the same faulty position. An attempt to bring about proper occlusion should be undertaken at almost any reasonable age, but the result would be in proportion to the time when it was undertaken. Most of the abnormalities became worse with the

advance of age. The pediatrist was in the position to sound the warning and should do so as soon as he noticed the "habitual open mouth" in the infant. Dr. Zentler called attention to the good influence of breast feeding in aiding the natural development of the maxilla and mandible. Later in the childhood the kind of nourishment that gave ample exercise through need of thorough masticaion would add materially to the development not only of the bones supporting the teeth but also to all bones connected with them. The age of three or four years was none too early to anchor appliances on the teeth. Dr. Zentler presented casts and photographs showing the results of faulty occlusion.

**Diagnosis and Treatment of the Inflammatory Affections of the Nasal Accessory Sinuses in Children.**—Dr. Seymour Oppenheimer presented this paper. He said that sinusitis occurred much more frequently in children than was generally supposed, and that this applied not only to older children but to small children and to infants. It seemed possible that many cases of meningitis were the result of unrecognized inflammation of some of the sinuses. In early life they varied greatly in size and shape and were surrounded by much softer bone than at a later period of life. There was also a much more profuse development of the lymphatic and vascular systems and the mucosa was in the most intimate relation with the osseous tissue, so that a slight inflammation of the former must produce some pathological change in the latter. Dr. Oppenheimer had not found chronic sinusitis as frequent in the child as in the adult, but acute and subacute sinusitis were common. Many instances of post-nasal catarrh in children were but symptoms of some inflammatory changes of the adjacent sinuses. Inflammatory affections of the ethmoid cells were most important in the child, these cells and the antra being more frequently involved than the frontal and sphenoidal sinuses. In the child the middle turbinate body was essentially a portion of the ethmoid area just as in the adult, although its anterior end was thinned out, was small, and ran parallel to the perpendicular palate, so that the lower border was deflected inward. As the internal wall of the orbital fossa formed the external boundary of the ethmoid the possibility of orbital symptoms as a complication of ethmoid infection was apparent and this relationship was important because of the extreme thinness of the ethmoidal-orbital wall. Previous to the seventh or eighth year the frontal sinus was not usually developed, though it might be present as early as the fifth year. At the eighteenth year its full development was accomplished. Its anatomical and surgical relations were like those of the adult except that its relation to the cranial cavity on account of the thin posterior wall was most intimate and this should be considered in relation to inflammatory processes. The sphenoidal cavity might be noted as early as the third year and was well developed by the seventh year. Its lateral walls were largely within the cranial cavity and this should be considered in the relation to the development of obscure cases of basal meningitis, also its intimate relations laterally and superiorly with the internal carotid artery and cavernous sinus. The recognition of sinusitis in the child was more difficult than in the adult, as the symptoms were more obscure and rarely characteristic. The frequency of the infectious diseases in childhood and the concomitant inflammatory changes in the nasal mucosa explained why the sinus should be involved during this period. In the newborn sinusitis might occur as a result of the infection by the vaginal discharges from the mother or as a result of instrumental delivery and the resultant purulent inflammation which involved the soft osseous antral walls. This was true sinusitis and not a tuberculous caries. As a rule affections of the antrum occurred during second dentition and infrequently errors in the development of the teeth might act as an exciting cause of the empyema. The ethmoid labyrinth in the older child was especially liable to become involved in all the inflammatory affections of the nasal mucosa and in coryza and the contagious diseases of children these cells were affected in almost every instance and a continuation of the infection might account for suppurating ethmoiditis in later life. In the recognition of these conditions transillumination was practically valueless in children. The use of carefully made *x*-ray plates was the most valuable diagnostic medium they possessed. The presence of frequent headache should aways occasion suspicion of sinus inflammation. In acute sinusitis pain of an aching character was almost invariably present at some time during the course of the inflammation. In chronic cases it was very frequently absent unless secretions were retained under pressure. A marked symptom was the disappearance of pain with the beginning of a free nasal discharge. The presence of discharge, especially if unilateral and purulent or semi-purulent in character, was always of diagnostic value, especially if intermittent. The location of the discharge was of great diagnostic value in determining which sinus was affected and this was determined as in the adult. Aprosexia and disturbance in the general health were more or less inevitable concomitants of chronic purulent sinusitis. In the so-called strumous child, where there was purulent nasal discharge, excoriated upper lip and marginal bleparitis, purulent sinusitis of the antrum and ethmoid cells usually existed; and while serious organic changes were not present when they did occur the ethmoid cells were usually the ones involved. Serious orbital complications might ensue as a result of pathological changes in the correlated vascular sinuses. In the milder forms a symptom of diagnostic value was edema of the eye-lids. In inflammatory processes of the maxillary antrum it was not uncommon to find involvement of the osseous structures of the superior maxilla. In the majority of cases of pansinusitis the ethmoid system was usually the primary source of infection. Frontal sinus involvement did not occur so often in the child as in the adult and was recognized as in the adult. Purulent sinusitis was the most difficult of recognition as it was practically always combined with ethmoidal changes and the symptoms were not characteristic. Severe occipital headache and dizziness were suggestive of retained secretions in this sinus. The discharges were scant and usually inspissated in the nasopharynx, or along the posterior portion of the vomer and floor of the choanæ and frequently the condition could not be recognized until exploration of the interior sinus had been made. This should not be done until the presence of other sinus affections of a purulent character had been eliminated. The treatment of sinusitis in the child should always aim to destroy as little tissue as was consistent with obtaining permanent results, and the intranasal mucosa should be preserved as far as possible. Palliative treatment would cure the majority of cases of acute sinus inflammation. Warm alkaline sprays and a weak solution of epinephrin solution should be used to reduce the congested mucosa. In the severe cases rest in bed, laxatives, or other measures that the individual case might demand should be instituted. Hot vapor inhalations and the use of negative pressure to drain the sinuses had a distinct sphere of usefulness. The general health should be attended to if satisfactory results were to be secured from treatment of the local condition. In operative interference it should be emphasized that as little as possible of the turbinal tissue be removed. When possible drainage should be obtained through the natural openings, and to effect this it was proper to remove enough osseous tissue at such points as might be required. It should be emphasized that any enlargement of the turbinated bone was a serious obstacle to the cure of inflammatory changes in any sinus until this was relieved. Free drainage in this connection also meant free nasal respiration and must be taken into consideration on the surgical treatment of these cases. It was essential that when pus was found it should be evacuated and granulations and necrosed tissue be removed. In conclusion Dr. Oppenheimer said that it had been his experience that in young children radical operative procedures for the relief of purulent sinusitis were rarely indicated and were not as productive of satisfactory results as the more conservative intranasal procedures, and while the same might be said of older children, yet, as they approached the adult type, the same indications for treatment and the same operative procedures applied as in the adult.

Dr. John McCoy said that accessory sinus disease in children was more common than was supposed, occurring frequently, but not diagnosed. Adenoids were largely responsible for these conditions as they were not only a focus of infection, but produced swelling of the tissues of the nose and indirectly were responsible for deviations of the septum; these conditions in turn caused deficient drainage of the accessory sinuses. The adenoids also interfered with drainage. Dr. McCoy, when he operated upon a child for adenoids, did not assure the parents that the child would breathe through his mouth after the operation, but, on the other hand, he told them that the child would probably have to have some of the turbinate tissue removed and also the palatal arch corrected by a dentist. Of the acute cases of sinusitis, 95 per cent. could be cured by rest in bed, attention to diet, laxatives, and, locally, adrenalin spray. In chronic cases the main question was one of drainage, and any obstruction to drainage from the frontal ethmoid or sphenoid region must be removed. Occasionally an external radical operation had to be resorted to. In conclusion Dr. McCoy reported two

cases of sinusitis that resulted in brain abscess, one was cured, and the other died.

Dr. Percy Fridenberg said that this subject was of great practical interest to the ophthalmic surgeon, who was not infrequently confronted with cases presenting ocular and orbital conditions which might be due to suppuration in one or more of the accessory cavities. It was important for diagnostic purposes to be able to exclude such involvement of the sinuses. The possibilities for ocular and orbital involvement were accentuated in infants and small children by the large size of the eye-socket as compared with the rest of the face, the intimate spacial relation with the neighboring sinuses, and the extreme richness and complexity of the vascular communications. Fortunately there were factors of safety in the sinuses of children, namely, their smallness and comparatively free drainage direct into an unobstructive nasal passage, and the fact that there had not been sufficient time for chronic inflammation with resultant changes in the mucosa, causing obstructive growths or bone disease. The rôle of adenoids was not to be denied. The mere mechanical obstruction caused in turn turbinate swelling, venous engorgement in the pharynx, spheno-maxillary, and ptergoid regions sufficient to bring about a decided disturbance of the orbital circulation and to produce exophthalmus or edema of the lids. The pain of accessory sinus disease might be simulated by syphilitic periostitis or osteomyelitis of the frontal, superior maxillary, or nasal bones. This specific disease as well as tuberculosis should always be borne in mind. Gonococcus infection in the new born might travel up through the lachrymal sac and conjunctiva and infect the orbit; in all cases of blennorrhea in the new born treatment of the nasal involvement was of prime importance. Where there was evident pus collection in or about the globe it was not wise to make incisions through the lids; little if anything could be gained by stabbing at random. The prime requisite in operative work was free drainage and that generally meant the removal of the ethmoid labyrinth and breaking through widely into the nasal cavities. If that were done they would not have relapses, protracted course of healing, or intracranial complications. In very young children they should strive to preserve the orbital margin on account of its importance for growth and development of the eye socket which had such an important bearing on facial symmetry. In the treatment of incipient, milder, or catarrhal cases of sinus involvement, Dr. McCoy had obtained excellent results with dry superheated air, charged with vapor of iodine, menthol, coryfin, chloral, and other medicaments. He used a fine eustachian or frontal sinus catheter and made a local application. Quinine and antipyrine internally as well as locally were of great value in shrinking up swollen membranes. The rational early treatment would prevent complications and make extensive surgical procedures infrequent if not unnecessary. The greatest aid to early treatment was early diagnosis and this depended on careful and frequent examinations. Routine inspection of the nares in children should be as familiar and usual a step as the examination of the ears. If this were the case they would not be told that these affections were rare.

Dr. Ernest Danziger believed that the high palate and the deviation of the nasal septum were caused by nasal obstruction, not only in the form of hypertrophic Luschka's tonsil, but by a general hypertrophy of the lymphoid tissue of the pharynx, and that associated with the latter condition there was a hypertrophy of the mucous membrane of the lower turbinals. Acute accessory sinus disease had a tendency to recover spontaneously, and it was only in the severe forms that a diagnosis was made. There were two causes which operated to make an acute sinus disease become chronic, namely, interference with drainage, and a constitutional predisposition, such as a luetic or tuberculous tendency. In the latter cases, general hygienic, dietetic or specific treatment was as important as the institution of local measures.

Dr. Edward A. Bogue said that but little had been said regarding the age at which operation should be performed for adenoids. Adenoids if carefully looked for were often found during the first year of life and the result was that the lungs, and consequently the thorax, were imperfectly developed. A large proportion of mouth breathers were more prone to have children's diseases than those who breathed normally. It was within the province of the pediatrist to watch for adenoids. If they were not removed until the tenth year or later the mouth would not close, and further treatment was necessitated.

Dr. Godfrey R. Pisek said that he believed that most of the children suffering from sinusitis came to the pediatrist first, and that in going over the dispensary reports one would find that this diagnosis was rarely made. The diagnosis might be easily made in some cases; others were obscure and were mistaken for typhoid fever or incipient meningitis. In these cases one should make the diagnosis by exclusion, watching with great care for any discharge that came posteriorly from one nasal orifice, and they should take note of any pain that began in the frontal sinus. Dr. Pisek thought that they should not harp too much on adenoids as the cause of defective dental arches because there were other factors in the etiology, such as the nutritional, the environment, and certain vicious habits as the sucking of false nipples, pacifiers, etc. It was important that the deciduous teeth be properly cared for; if they were decayed it was right that they should be filled.

Dr. Charles Gilmore Kerley said that he had met with these cases of accessory sinus disease but rarely, seeing perhaps only two or three such cases in a year. He felt confident that the deformities in the dental arches occurred during the first eighteen months of life, and that adenoids were present in the great majority of these children. He agreed that thumb sucking and kindred habits tended to produce or establish a deformity in the vault of the pharynx. Dr. Kerley emphasized the point that deformity of the dental arches had a bearing on morbidity and that poorly nourished children were more liable to develop faulty dental arches. The presence of adenoids added to the continuance of the condition and assisted in establishing the deformity in the dental arches.

Dr. Henry Koplik thought that both the papers were excellent and were a help to both the pediatrist and the specialist. These deformities were found in infants, *in utero*, and this congenital element was very often overlooked. There were other etiological factors which should be taken into consideration, such as rickets and other diseased conditions of the bones. There was a question in his mind as to whether mouth breathing had anything to do with the formation of dental arch deformities. Abnormal conditions such as adenoids were rare at birth and only developed later on. He did not believe that the mechanical element played as great a rôle as was ascribed to it. There was no doubt but that many of the cases of sinus disease were overlooked or only discovered accidentally; this conclusion was borne in upon him because no attempt had been made to formulate the symptoms by means of which the condition could be discovered. The physician and the surgeon should co-operate in the care and diagnosis of these cases.

Dr. Francis J. Quinlan did not think that the last word had been uttered on this subject. He was inclined to think that the lymphatic tissues played a very important part in the etiology of this condition. Deviations of the nasal septum could be brought about by these lymphoid masses. He was not convinced that he had seen many of these cases of sinusitis.

Dr. Frank E. Miller discussed in detail the relation of arches, normal and abnormal, and of accessory sinuses in relation to respiration and voice values. He showed that a comparison of the vowel sounds as uttered by children with normal dental arches and nasal conditions with those uttered by children with defects would demonstrate conclusively the deleterious effects of deformities on voice values. He called attention to the effect of tracheotomy on the nasal development from loss of voice vibrations upon them, especially the three turbinated bones; septum, dome, hardpalate, teeth, epiglottis, and thyroid cartilage were of special value in the production of the seven limited overtones on the fundamental chordal tone in the reinforcing of vocal resonance. Dr. Miller cited the case of a child with monotone voice that was due to tonsillectomy, where the surgeon cut off the entire posterior pillar; gradually the child recovered a fair speaking voice, but preferred to speak on one pitch. Injuries to the palato-pharyngeal and palato-glossi muscles were most serious as they impaired palate and tongue action in song and speech construction, as well as overtone. In adenoid removals if the posterior pharyngeal wall was injured and dragged off it could be replaced and made to grow back, but should the superior constrictor muscle be injured, the phonetic value of the upper register of the voice would be altered.

Dr. Miller introduced Dr. Holmes Merton who, at his suggestion, had made the charts which were exhibited and which showed the accurate location and geography of every vowel and consonant; every acoustic resonator for seven overtones of the voice; the anastomosis of nerves supplying phonetic efforts, muscles, nerves, etc., for nose, tongue, mouth and throat; the entire vocal system based on units of voice construction, and the autonomy of the unit of distribution of force in voice construction or analogous action and construction of the palato-pharyngei from the superior constrictors of the uvula, and to that of the vocal cords themselves.

Dr. Linnaeus E. LeFetra said that he had never made a diagnosis of nasal accessory sinusitis in children, and he was glad to have heard the paper calling attention to the condition. Undoubtedly many cases of persistent "colds" in the head were due to inflammation of some of the sinuses. Most of these cases, he believed, got well under conservative treatment. Adenoids should be operated upon early of they produced any symptoms; he had removed them from infants as young as one week. The high arched palate often appeared in babies but a few weeks old, and in such cases there must be a congenital or hereditary factor, since there was not time for the adenoids to produce such a condition.

Dr. William W. Carter said that any extensive injury to the posterior pillars certainly injured the voice, and it was his opinion that in many of these operations there occurred an injury to the posterior pillars. He believed that when the tonsil was properly enucleated that the pillars were not injured and that the voice was not impaired, but, on the other hand, was frequently improved by such an operation.

Dr. Pisek called attention to the work of Dr. Jellenek of Prague, who advocated carrying out an examination of the voices of school children, and if he found that the singing voice was abnormal he carefully looked for the cause.

Dr. Sidney V. Haas believed that high and abnormal dental arches were not in themselves the result of adenoids in most cases. Special stress should be laid on the statement that high dental arches might be entirely normal and were so when the "bite" was perfect.

Dr. Thomas S. Southworth emphasized the importance of looking for these cases of accessory sinus disease; if these cases were not borne in mind, as well as many other conditions like otitis media and pyelitis, for instance, they would not be discovered. As a rule these cases of accessory sinus disease were pointed out to them by the rhinologist; he made the diagnosis of acute or subacute inflammation of these sinuses. Dr. Southworth reported the case of a boy who had had for some years a persistent anemia, and the anemia would not yield to any of the methods of treatment employed. It was evident that there was present a type of toxemia which resulted from the changes that were going on in the accessory sinuses and the child was now about to be operated on. In the subacute cases it was also probable that these patients were "germ carriers" and caused repeated outbreaks of infectious colds in their families.

Dr. Walter Lester Carr said that these vicious circles referred to could not be helped. There was no doubt but that they recognized more cases of sinus disease than formerly, and this was because they were now looking for them.

Dr. Herman Schwarz said it should be remembered that they could have nasal deformities without the presence of adenoids. There were a number of cases operated upon which were not improved. They were examining the noses of the children at Mount Sinai Hospital, and would make a report on the subject later.

Dr. Eli Long emphasized the importance of making a routine examination of the children who presented themselves for accessory sinus disease.

Dr. Zentler said he did not intend to confer the impression that adenoids must be present in all cases of narrowed dental arches. He did not know exactly what caused them. He believed that breast feeding would help to develop the dental arches. If adenoids were present in infants they should be removed in order to obviate any disturbance of the dental arches. He had frequently emphasized the importance of the care of the teeth in children. Dr. Pisek's point was a good one; if the decidual teeth were decayed or were not in proper occlusion, one did not do his duty unless he advised filling them and correcting the defective arches.

Dr. Oppenheimer referred to the splendid work that was being done by the orthodontist. He believed that there were factors other than adenoids present which were responsible for the narrowing of the dental arches. In certain cases of nasal obstruction the correction of this defect had no influence whatsoever on the dental arches. In many of these cases the employment of nasal and nasopharyngeal surgery was unnecessary and inadvisable. He had been surprised to note how a deflection of a nasal septum of considerable degree was overcome by the lateral spreading and widening of the maxillary arch. As to the controversial subject of a rapid or slow spreading of the dental arches he could not speak with authority. The frequency of nasal accessory sinus disease in children depended entirely on the alertness of the observer. One should expect to find inflammation of the accessory sinuses quite frequently, as the mucous membrane lining these cavities was continuous with that lining the nasal passage and the eustachian tube, and it was not rational to expect that the inflammation would be strictly limited to the nasal interior. He believed that careful examination of the nasal chambers in children would reveal many subacute and latent infections.

---

## CLINICS, DEPARTMENT OF PUBLIC CHARITIES

Calendar, January, 1913.

| | | | |
|---|---|---|---|
| **MONDAYS** | | | |
| *City Hospital* | Surgery | Dr. Dawbarn | 2:30 P.M. |
| *Neurological Hospital* | Neurology | Dr. McPhee | 2:00 P.M. |
| *Cumberland Street Hospital* (Brooklyn) | Surgery | Dr. Pallister | 2:30 P.M. |
| | Oral Surgery | Dr. Shea | 4:30 P.M. |
| | Rhinology and Laryngology | Dr. Stewart | 4:00 P.M. |
| *Kings County Hospital* (Brooklyn) | Gynecology | Dr. McNaughton | 9:00 A.M. |
| **TUESDAYS** | | | |
| *City Hospital* | Surgery | Dr. Collins | 10:30 A.M. |
| | Ophthalmology | Dr. Gilfallau | 2:00 P.M. |
| | Dermatology | Dr. Bronson | 2:30 P.M. |
| *N. Y. City Children's Hospitals & Schools*, Randall's Island | Orthopedics | Dr. Ogilvy | 10:00 A.M. |
| *Cumberland Street Hospital* (Brooklyn) | Gynecology | Dr. Burnham | 1:00 P.M. |
| | Ophthalmology and Otology | Dr. Warner | 3:00 P.M. |
| | Surgery | Dr. Ritch | 2:30 P.M. |
| *Kings County Hospital*, (Brooklyn) | Obstetrics | Dr. Commiskey | 10:00 A.M. |
| | Surgery | Dr. Bristow | 2:00 P.M. |
| | Genito-urinary Surgery | Drs. Morton and Fraser | 2:00 P.M. |
| *Coney Island Hospital* | Surgery | Drs. Fisk and Bogart | 10:30 A.M. |
| | Medicine | Drs. Hall and Nash | 3:30 P.M. |
| **WEDNESDAYS** | | | |
| *City Hospital* | Surgery | Dr. Dawbarn | 9:00 A.M. |
| | Genito-urinary Surgery | Dr. Fuller | 2:00 P.M. |
| | Obstetrics | Dr. Dorman | 2:30 P.M. |
| *Metropolitan Hospital* | Surgery | Dr. Harrington and Ostrom | 2:30 P.M. |
| Jan. 8 | Dermatology | Dr. Dearborn | 2:30 P.M. |
| Jan. 8 | Rhinology and Laryngology | Dr. Foster | 2:30 P.M. |
| Jan. 15 | Dermatology | Dr. Dearborn | 2:30 P.M. |
| Jan 15 | Genito-urinary Surgery | Dr. Carlton | 2:30 P.M. |
| Jan. 22 | Medicine | Dr. Rankin | 2:30 P.M. |
| Jan. 22 | Medicine | Dr. Hathaway | 2:30 P.M. |
| Jan. 22 | Rhinology | Dr. Foster | 2:30 P.M. |
| Jan. 22 | Neurology | Dr. Howard | 2:30 P.M. |
| *Neurological Hospital* | Neurology | Dr. Maloney | 11:00 A.M. |
| *Kings County Hospital* (Brooklyn) | Dermatology | Dr. Winfield | 1:00 P.M. |
| | Orthopedics | Dr. Truslow | 9:00 A.M. |
| | Orthopedics | Dr. Napier | 2:00 P.M. |
| *Coney Island Hospital* | Pediatrics | Drs. Beck, McQuillian, Pendelton and Van Wart | 3:30 P.M. |
| **THURSDAYS** | | | |
| *City Hospital* | Medicine | Dr. Evans | 9:00 A.M. |
| | Medicine | Dr. Brooks | 2:30 P.M. |
| | Gynecology | Dr. Stearns | 2:00 P.M. |
| *Cumberland Street Hospital* (Brooklyn) | Gynecology | Dr. Burnham | 1:00 P.M. |
| | Surgery | Dr. Ritch | 2:30 P.M. |
| | Rhinology and Laryngology | Dr. Stewart | 4:00 P.M. |
| *Kings County Hospital*, (Brooklyn) | Obstetrics | Dr. Commiskey | 10:00 A.M. |
| | Obstetrics | Dr. Judd | 10:00 A.M. |
| | Otology | Dr. Alderton | 1:00 P.M. |
| | Surgery | Dr. Bristow | 2:00 P.M. |
| | Pediatrics | Dr. Parrish | 4:00 P.M. |
| *Coney Island Hospital* | Gynecology | Drs. McEvitt and Mills, Mayne and Rankin | 10:30 A.M. |
| | Laryngology and Rhinology | Dr. Tucker | 1:30 P.M. |
| | Surgery | Drs. Murphy and Lack | 3:00 P.M. |
| **FRIDAYS** | | | |
| *City Hospital* | Laryngology and Rhinology | Dr. Dougherty | 2:30 P.M. |
| *Neurological Hospital* | Neurology | Dr. Abrahamson | 9:00 A.M. |
| *Cumberland Street Hospital* (Brooklyn) | Surgery | | |
| | Ophthalmology and Otology | Dr. Pallister | 2:30 P.M. |
| | | Dr. Warren | 3:00 P.M. |
| | Oral Surgery | Dr. Shea | 4:30 P.M. |
| *Kings County Hospital* (Brooklyn) | Gynecology | Dr. McNaughton | 9:00 A.M. |
| **SATURDAYS** | | | |
| *City Hospital* | Pathology: Demonstrations and Lantern Exhibitions | Dr. Larkin | 2:00 P.M. |
| *Neurological Hospital* | Neurology | Dr. Jeleffe | 2:00 P.M. |
| *Kings County Hospital*, (Brooklyn) | Obstetrics | Dr. Commiskey | 10:00 A.M. |
| | Surgery | Dr. Bristow | 2:00 P.M. |
| | Medicine | Dr. Stivers | 3:30 P.M. |

All registered Physicians are cordially invited to attend these Clinics. Admission cards, valid until October 1, 1913, may be obtained on personal application at The New York Academy of Medicine, 17 West 43d St., Manhattan, and at The Medical Society of the County of Kings, 1313 Bedford Ave., Brooklyn.

# State Medical Licensing Boards.

## STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS, STATE OF GEORGIA.

*May, 1912.*

### ANATOMY.

1. Name bones of the head. What are the Wormian bones?
2. Name articulations of occipital and of parietal bones. Name bones articulating with humerus.
3. Name divisions of vertebral column, giving number of bones in each division. What are distinguishing characteristics of cervical vertebræ?
4. Describe briefly the pleura. What is contained in the middle mediastinum. Name the openings in the pharynx.
5. Locate and briefly describe the gall-bladder. Give anatomical relations of appendix vermiformis.
6. Name abdominal viscera wholly covered with peritoneum; those partly covered.
7. Give relations of womb, ovaries, and Fallopian tubes.
8. Name the nerves of the special senses. Give origin of eighth and ninth pairs. In which part of spinal cord are motor and sensory nerve fibers located, respectively?
9. Give origin and insertion of biceps muscle. Locate pectoralis major and minor muscles. Give origin and insertion respectively.
10. Name component parts of the spermatic cord. Name divisions of male urethra. Where are ureters located?

### PHYSIOLOGY.

1. What is the normal temperature of the body? Give two physiological reasons for increased temperature.
2. Give in detail the functions of the liver and gall-bladder.
3. Name the physical properties of normal urine.
4. Locate the spleen and thyroid gland and give the function of each.
5. What is aphasia? Give the different forms and causes of each.
6. What is the difference in the development of the motor and sensory nerves?
7. What is respiration? Name four things that happen to the blood in the lungs.
8. Describe the red and white blood corpuscles and the work of each.
9. Describe mouth, gastric, and intestinal digestion.
10. Why and how should physicians cooperate with all that promotes community health?

### MATERIA MEDICA AND THERAPEUTICS.

1. Give treatment of syphilis.
2. Define galactagogue, sialagogue, hydragogue, cholagogue, and an anthelmintic. (*a*) Name a drug as an example of each.
3. What are the physiological effects of digitalis and how does it differ from strophanthus? (*a*) In what diseases would you administer digitalis?
4. (*a*) Define Materia Medica. (*b*) Therapeutics.
5. Write a prescription for a collyrium and for a suppository. (*a*) Give the treatment of scabies.
6. Give treatment of (*a*) opium poisoning, (*b*) carbolic acid poisoning (*c*) bichloride of mercury poisoning.
7. Name five official preparations of iron; five of mercury.
8. Name three vasomotor stimulants; three vasomotor depressants.
9. Give the treatment of an acute case of dysentery.
10. Mention three drugs that are administered internally to arrest hemorrhage. (*a*) Name three to promote menstruation.

### PATHOLOGY.

1. Differentiate pyemia and septicemia.
3. Definition of inflammation.
4. Name the four orders of phenomena characterizing an inflammation.
5. Why will an incised wound heal more readily than a contused one?
6. Why is a punctured wound more liable to produce tetanus than an incised one?
7. Difference between aërobic and anaërobic bacteria.

### PRACTICE.

1. (*a*) How would you make a diagnosis of typhoid fever? (*b*) What drug would you use to differentiate typhoid from malarial fever? (*c*) What typhoid prophylactic measures would you employ in typhoid fever? (*d*) How would you treat intestinal hemorrhage of typhoid fever?
2. (*a*) Make differential diagnosis between bronchopneumonia and croupous pneumonia. (*b*) Differentiate unresolved pneumonia and pyemia.
3. (*a*) Differentiate between mitral insufficiency and aortic insufficiency. (*b*) What do you understand by broken compensation of the heart, and give treatment for same.
4. Make diagnosis of acute uremia and give treatment.
5. Give differential diagnosis of catarrhal and obstructive jaundice and treatment of each.
6. Differentiate tonsillitis and diphtheria and give treatment of each.
7. (*a*) Give the symptoms, diagnosis, and treatment of uncinariasis. (*b*) Is it limited to children only?
8. What is the opsonic index?
9. (*a*) Burns are divided into how many degrees? (*b*) Give treatment for burns. (*c*) What complications to be looked for in burns?
10. Differentiate concussion, apoplexy, drunkenness, and uremic coma.

---

## ANSWERS.

### ANATOMY.

1. *Bones of the head:* Occipital, two parietal, two temporal, ethmoid, sphenoid, frontal, two lacrymal, two malar, two nasal, two palate, two superior maxillary, inferior maxillary, vomer, and two inferior turbinated.

The *Wormian bones* are irregular, isolated, supernumerary bones, situated between some of the cranial bones; they are generally found in the lambdoid suture and in the fontanelles, and vary greatly in size and number.

2. *Articulations of occipital bone:* Two parietal, two temporal, sphenoid, and atlas.

*Articulations of parietal bone:* Occipital, frontal, temporal, sphenoid, and opposite parietal.

*Articulations of humerus:* Scapula, ulna, and radius.

3. The vertebral column is divided into: Cervical division, with seven bones; dorsal, or thoracic, with twelve bones; lumbar, with five bones; sacral, with five bones, and coccygeal, with four bones.

The *cervical vertebrae* are distinguished by possessing a foramen in the transverse process. Further, they are smaller than those in the other regions; they have no facets for the ribs; the spinous processes are generally short and bifid; the spinal foramen is large and triangular; the superior articular process is directed upward and backward, and the inferior articular process is directed downward and forward.

4. "The *pleuræ* are two serous sacs enclosing and investing the lungs. Each pleura consists of a visceral and parietal layer. The *visceral* portion covers the lungs, and the *parietal* layer lines the inner surface of the chest walls, the upper surface of the diaphragm, and the sides of the pericardium. The visceral and parietal layers of the corresponding pleura become continuous in front and behind the root of the lung; and below the root a fold, the *ligamentum latum pulmonis*, extends downward along the inner surface of the lung to the diaphragm. The mediastina are formed by the visceral layers of each side approaching one another toward the median line." (*Aids to Anatomy.*)

The *middle mediastinum contains:* The pericardium, the heart, ascending aorta, part of superior vena cava and vena azygos major, bifurcation of trachea and the two bronchi, pulmonary artery, pulmonary veins, phrenic nerves, and lymphatic glands.

*Openings in the pharynx:* Two Eustachian tubes, two posterior nares, mouth, larynx, and esophagus.

5. The *gall-bladder* is a conical bag placed in a fossa on the under surface of the right lobe of the liver. Its upper surface is attached to the liver, and its fundus and posterior surfaces are invested by peritoneum reflected from the adjacent surface of the liver. The body is in relation in front with the liver, and behind with the first part of duodenum, the pylorus, and the hepatic flexure of colon. The fundus is in contact with the parietes opposite the ninth right costal cartilage.

*Relations of vermiform appendix.* Owing to the variable position of the appendix, these are not definite. As a rule, the appendix is given off from the lower, posterior surface of the cecum, and points upward and to the left, but it may hang down into the pelvic cavity, or take almost any other position with reference to the lower end of the cecum. The point at which the appendix joins the cecum is generally indicated on the anterior abdominal wall by *McBurney's point.* (A line is drawn from the anterior superior spine of the ilium to the umbilicus, and a point

is marked off on this line at a distance of two and a half inches from the spine of the ilium.)

6. (*a*) *Wholly covered with peritoneum:* Stomach, first part of duodenum, jejunum, ileum, cecum, transverse colon, sigmoid flexure, first part of rectum, liver.

(*b*) *Partially covered with peritoneum:* Second and third part of duodenum, ascending and descending colon, middle part of rectum, bladder.

(*c*) *Without peritoneal investment:* Pancreas and kidneys.

7. The *uterus* is in front of the rectum, behind the bladder; it has the broad ligament on each side; above and a little behind are coils of small intestine; and below is the vagina. The *Fallopian tubes* are situated in the upper margin of the broad ligament; in front and behind are the broad ligament; at the inner end is the uterus, and at the outer end the ovary. The *ovaries* are situated in the posterior layer of the broad ligament, below the Fallopian tube. Their position is very variable. In front is the broad ligament; behind, coils of small intestine; above, the Fallopian tube; on the outer side is the wall of the pelvis; on the inner side, the broad ligament.

8. The *nerves of special sense* are: First, or olfactory; second, or optic; eighth, or auditory; ninth, or glossopharyngeal (in part). *Origin of eighth nerve:* Between the pons and restiform body, from the auditory nuclei and striæ acusticæ in the floor of the fourth ventricle. *Origin of ninth nerve:* From the upper part of the medulla in the groove between the olive and the restiform body, and from the floor of the fourth ventricle.

*Motor fibres* are located in the direct pyramidal tract, the crossed pyramidal tract. *Sensory fibres* are located in the direct cerebellar tract, the anterolateral ascending tract, Burdach column, and Goll's column.

9. Biceps. *Origin:* Glenoid cavity and coracoid process of scapula. *Insertion:* Tuberosity of radius.

The *Pectoralis major* is situated at the upper and forepart of the chest, in front of the axilla. The *Pectoralis minor* is situated at the upper and front part of the thorax, beneath the Pectoralis major.

Pectoralis major. *Origin:* Anterior surface of inner half of clavicle, anterior surface of sternum, from the cartilages of the second to sixth ribs, and from the aponeurosis of the external oblique of the abdomen. *Insertion:* Into the outer bicipital ridge of the humerus.

Pectoralis minor. *Origin:* From third and fourth and fifth ribs, just external to the cartilages, and from aponeurosis over intercostal muscles. *Insertion:* Into coracoid process of scapula.

10. The *spermatic cord* consists of the vas deferens with artery to the vas, spermatic artery, and pampiniform plexus of veins forming spermatic vein above, sympathetic nerves, the cremasteric artery, the genital branch of the genitocrural nerve, lymphatics, together with some areolar tissue; it extends from the internal abdominal ring to the testis, passing in its course along inguinal canal, from which it emerges by the external abdominal ring, and thence in front of the pubes to the scrotum. The vas deferens is placed at the back of the cord.

The *male urethra* is divided into three parts: The prostatic, the membranous, and the spongy.

The *ureters* are situated in the back part of the abdominal cavity and in the pelvis; they pass from the pelvis of the kidneys to the back part of the base of the bladder.

## PHYSIOLOGY.

1. The *normal temperature of the body* is about 98.6° F. *Two physiological reasons for increased temperature:* Exercise and ingestion of food.

2. The *functions of the liver* are: (1) The secretion of bile; (2) the formation of glycogen; (3) the formation of urea and uric acid; (4) the manufacture of heat; (5) the conversion of poisonous and harmful substances into inert material.

The *function of the gall-bladder* is to serve as a reservoir for the bile between the time of its manufacture by the liver and its being poured into the duodenum.

3. *Normal urine* is a yellowish fluid secreted by the kidneys to the amount of about 1,200-1,500 c.c. daily; specific gravity, about 1,015 to 1,025; acid reaction (due to acid sodium phosphate); it has a characteristic odor and a salty taste. Its normal constituents are: Water, urea, uric acid, urates, hippuric acid, kreatin, kreatinin, xanthin, hypoxanthin; sulphates, chlorides, and phosphates of sodium and potassium; phosphates of magnesium and calcium; nitrogen, and carbon dioxide.

4. The *spleen* is situated below the diaphragm, between the diaphragm and the fundus of the stomach; it is chiefly in the posterior part of the left hypochondriac region, but it extends also into the epigastric region.

The *thyroid* is situated at the front and sides of the neck and extends up on each side of the larynx; the isthmus generally crosses the second and third rings of the trachea.

*The function of the spleen:* The following theories have been held: (1) It is a source of production of the white blood corpuscles; (2) it is a source of production of the red blood corpuscles during fetal life; (3) it is a place where the red blood corpuscles are destroyed; (4) uric acid is produced in the spleen; (5) an enzyme is produced in the spleen and is carried by the blood to the pancreas, where it converts the trypsinogen into trypsin.

The *function of the thyroid* is not definitely settled: (1) it has some trophic function, regulating oxidation in the body, and it is supposed to have also a special influence on the vasomotor nerves, the skin, the bones, and on the sexual functions; (2) it is supposed to antagonize toxic substances; and (3) it produces an internal secretion.

5. "*Aphasia* is a morbid condition consequent on a cortical or subcortical lesion, whereby speech, writing, or reading may become impaired, either from an inability to co-ordinate the necessary movements involved in speech, or from a defective interpretation of sounds or visual impressions. . . . Speech involves a healthy continuity between the chief motor center in the left inferior frontal lobe and the visual and acoustic centers on the one hand and between the chief motor center and the muscles employed in speech or reading aloud on the other. The centers assigned to speech and writing are motor and sensory, distributed thus: (1) a motor (*glosso-kinesthetic*) speech center, in the third left frontal (Broca's convolution); (2) a motor (*cheiro-kinesthetic*) center for writing, in the posterior part of the second left frontal convolution; (3) sensory centers; (a) *auditory word center,* in the posterior part of the first temporal convolution; (b) the *visual word center,* in the angular gyrus. The motor centers connect with each other and the sensory centers by commissural fibers. The similar but subordinate centers in the right hemisphere have a limited capacity for taking over the functions of the left centers when these are destroyed. (1) Lesions of the glosso-kinesthetic center cause *motor aphasia*—the patient is unable to express himself in words, although there is no paralysis of articulation. (2) Lesions of the cheiro-kinesthetic center cause *agraphia*—the patient cannot express himself in writing. (3) Lesions of the visual word center in the angular gyrus cause *word blindness or alexia*—i. e. the patient can see print but cannot read it. (4) Lesions of the auditory word center in the temporosphenoidal lobe cause *word deafness*—the patient hears but does not understand words.

6. *Motor nerve fibers* are developed in the gray matter beneath the aqueduct of Sylvius, beneath the floor of the fourth ventricle and in the anterior horns of the gray matter of the spinal cord.

*Sensory nerve fibers* are developed outside of the central nervous system, and later on become connected with it. The cells develop two processes, one of which passes toward the spinal cord, and the other toward the periphery.

7. *Respiration* is the process by which an interchange of gases takes place in the lungs; so that oxygen is introduced and carried to the tissues, and carbon dioxide is expelled. In the lungs the blood becomes red in color, it gains oxygen, it loses carbon dioxide, and it is cooled.

8. The *red corpuscles* are biconcave discs, about 1/3200 of an inch in diameter; they are non-nucleated, and there are about 4,500,000 or 5,000,000 of them in each cubic millimeter of blood. They contain hemoglobin.

The *white corpuscles* are spheroidal masses, varying in size, having no cell wall, and containing one or more nuclei; there are about 7,000 to 10,000 of them in each cubic millimeter of blood. They differ much in appearance, and are divided into (1) small mononuclear leucocytes, or lymphocytes, (2) large mononuclear, (3) transitional, (4) polynuclear, or polymorphonuclear, or neutrophile, and (5) eosinophile. They are all more or less granular, particularly the last two varieties named.

The *red blood cells* carry oxygen from the lungs to the tissues. The *white blood cells:* (1) Serve as a protection to the body from the incursions of pathogenic microorganisms; (2) take some nart in the process of the coagulation of the blood; (3) aid in the absorption of fats and peptones from the intestine, and (4) help to maintain the proper proteid content of the blood plasma.

9. Digestion. (1) *In the mouth* the food is crushed, mixed with saliva, and reduced to a pulp; a certain amount of starch converted into maltose and rendered slightly alkaline. Fats and proteids are unaltered. (2) *In the stomach,* the contents are rendered acid, conversion of starch into sugar ceases, connective tissue of fats is dissolved and fats are set free. Proteids are dissolved and

peptone formed. The albuminous foods are dissolved for the most part, and a grumous mixture of peptones, liquid fats, and starches is formed, which is termed chyme, and is gradually passed through the pylorus into the intestine. (3) In the *small intestine* the chyme is mixed with the bile and the pancreatic juice; the reactions become alkaline. Proteids are split up into proteoses and peptones; starches are converted into maltose; fats are emulsified and saponified; and the products of digestion are now ready for absorption.

10. The physician should consider it his duty and privilege to aid the Board of Health in disseminating knowledge and preventing disease. He should also avail himself of every opportunity to teach his patient and others the principles of hygiene.

MATERIA MEDICA AND THERAPEUTICS.

1. *Treatment of syphilis:* The management of the local sore consists in local cleanliness mainly. If the diagnosis is absolutely certain, mercury may be commenced at once, and may avert even secondary symptoms; but it is often advisable to wait till these appear before commencing specific treatment. Treatment consists in the early stages in the administration of one or other of the preparations of mercury. This can be given for long periods without producing salivation or diarrhea. Treatment must not be stopped when symptoms have disappeared, but must be continued for two or three years. Where symptoms are more urgent and a rapid effect is desired inunction of blue ointment ʒj daily or hypodermic injection of corrosive sublimate gr. ⅛ every second day may be practised, or calomel suspended in sterile oil may be injected into the gluteal muscles once a week. The condition of the mouth must be looked to and smoking should be forbidden if there are lesions in the mouth. In the tertiary stages iodide of potassium to a great extent takes the place of mercury, but the two are often advantageously combined. Doses of from 5 to 20 grains thrice daily usually suffice, but in cerebral syphilis the drug must be rapidly pushed to even large doses. In every case, besides treating the specific disease, the general health must be sedulously cared for. Salvarsan is now often used; it may be given subcutaneously, intravenously, or intramuscularly. It should be used with caution. (From Wheeler's *Handbook of Medicine.*)

2. *A galactagogue* is an agent which increases the secretion and flow of milk; example, pilocarpine. A *sialagogue* is an agent which increases the flow of saliva, as pyrethrum. A *hydragogue* is a cathartic which removes a large quantity of water from the vessels and tissues, as elaterium. A *cholagogue* is a purgative which stimulates the discharge of bile, with free purgation, as rhubarb. An *anthelmintic* is an agent which destroys or expels intestinal worms, as quassia.

3. DIGITALIS. *Physiological action:* It is a gastrointestinal irritant, it slows the rate of the heart, prolongs diastole, increases the force of the heart, it contracts the blood-vessels, and causes a rise in blood pressure, it also acts as a diuretic.

*Therapeutic use:* Digitalis is indicated in diseases of the heart: (1) when the heart action is rapid and feeble, with low arterial tension; (2) in mitral lesions when compensation has begun to fail; (3) in nonvalvular cardiac affections; (4) in irritable heart, due to nerve exhaustion. Digitalis is contraindicated in diseases of the heart: (1) in aortic lesions when uncombined with mitral lesions; (2) when the heart action is strong, and arterial tension high. Digitalis is also a diuretic; and it is also used in some forms of nephritis, exophthalmic goiter, pneumonia, chronic bronchitis, etc.

*Digitalis differs from strophanthus* in that it (digitalis) acts more slowly, has a more lasting effect, is more certain, and is cumulative in its action.

4. *Materia medica* is that branch of pharmacology which treats of the various substances used as medicines.

*Therapeutics* treats of the science and art of healing.

5. *A collyrium:*

℞. Zinci sulphatis.
Ferri sulphatis.
Cupri sulphatis.
Alumnis aa gr. j.
Aquæ destillatæ ʒj. M.
Fiat collyrium.
Sig.: Use on conjunctiva of eyelid, with a brush; and then wash it off with clean water.

*A suppository:*

℞. Extracti opii gr. vj.
Fluidextracti belladonnæ gr. ss.
Extracti hyoscyami gr. ij.
Olei therbromatis q.s. M.
Fiant suppositoria No. vj.
Sig.: Insert one into the rectum morning and night.

*Treatment of scabies* "consists in a protracted bath with soap and hot water, followed by the application of sulphur ointment (ʒi to ʒi) or other parasiticide every night for one week. In the meantime the bed-linen and underclothing should be sterilized by heat. At the end of a week another bath should be taken and some sedative ointment or lotion should be prescribed. Sulphur may be substituted by beta-naphthol, balsam of Peru, styrax, tar, staphisagria, etc." (*Pocket Cyclopedia.*)

6. *Treatment of opium poisoning:* "Wash out the stomach with a dilute solution of potassium permanganate, leaving about 500 c.c. in the stomach, and maintain the respiration. In the first or second stage the 'ambulatory treatment' should be adopted to prevent, if possible, the establishment of the third stage. If this stage develop, the main reliance is to be placed in maintaining the respiration by artificial methods, until the poison has been eliminated. Strong coffee, or caffein, by the mouth or rectum, are of benefit. The same cannot be said of atropin. The urine should be drawn by the catheter."

*Treatment of carbolic acid poisoning:* Wash out the stomach with pure alcohol, then with water; or give a soluble sulphate such as sodium sulphate.

*Treatment of bichloride of mercury poisoning:* Give milk or white of egg in moderate quantity, and follow with an emetic.

7. *Five official preparations of iron:* Reduced iron, ferrous sulphate, ferric chloride, soluble ferric phosphate, and iron citrate.

*Five official preparations of mercury:* Hydrargyrum cum creta, massa hydrargyri, hydrargyri chloridum mite, hydrargyri chloridum corrosivum, and liquor arseni et hydrargyri iodidi.

8. *Three vasomotor stimulants:* Ergot, belladonna, and strychnine. *Three vasomotor depressants:* Amyl nitrite, aconite, and alcohol.

9. *The treatment of acute catarrhal dysentery* "consists of rest in bed and liquid diet. Rochelle salts (ʒ½) or Epsom salts (ʒ½) should be given to cleanse the bowels thoroughly. Castor oil (ʒi) with laudanum (gtt. 20) may be used. Pain is relieved by opium, alone or combined with bismuth, subnitrate, cocain, or belladonna. Hope's camphor mixture (ʒ2) may be administered every 3 hours. The colon may be irrigated every 2 hours with lukewarm water or starch-water containing laudanum (3½). (*Pocket Cyclopedia.*)

10. *Three drugs administered internally to arrest hemorrhage:* Ergot, hamamelis, digitalis. *Three to promote menstruation:* Manganese dioxide, aloes, and cantharides.

PATHOLOGY.

1. In *septicemia* there are microorganisms present and multiplying in the blood. In *pyemia,* in addition to the above, particles of blood-clot carry microorganisms to parts distant from the original source, and there set up metastatic abscesses.

2. *Inflammation* is the name given to the series of changes which occur in a part as the result of injury, provided such injury is not sufficient to at once destroy the structure and vitality of the tissue.

3. (1) Changes in the blood-vessels; (2) changes in the circulation; (3) departure of plasma, and corpuscles from the blood-vessels; and (4) changes in the perivascular tissues.

4. In the incised wound there is only a thin film of tissue which is devitalized, the edges are clean cut and are readily put in apposition. In a contused wound the tissues are bruised and devitalized, and so healing processes are delayed.

5. The tetanus bacillus is anaerobic, and hence can live and thrive in a punctured wound, where there is little or no oxygen. An incised wound, on the other hand, offers no such favorable condition.

6. *Aerobic bacteria* will only live and grow in the presence of oxygen; *anaerobic bacteria* will only live and grow if oxygen is absent.

PRACTICE.

1. (*a*) *A diagnosis of typhoid fever* may be based on: The peculiar temperature curve, the rose eruption, the enlarged spleen, a positive diazo-reaction, and a positive Widal test. (*b*) Quinine. (*c*) *Prophylaxis:* Flies should be kept out of the house as far as possible, by means of screens or otherwise; all discharges from the sick person must be disinfected; all utensils, dishes, etc., used by the patient must be thoroughly cleansed, and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed; after each attendance on a patient, physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over. (*d*) *Intes-*

*tinal hemorrhage* is tested by: Opium, lead acetate or calcium lactate; morphine or ergotin hypodermically; ice-bag over the cecum. The foot of the bed should be elevated, and the diet should consist of peptonized or malted milk.

2.

| CROUPOUS PNEUMONIA. | BRONCHOPNEUMONIA. |
|---|---|
| Generally a primary disease. | Generally secondary (to bronchitis or an infectious disease). |
| Age has little influence. | Generally found in very young or very old. |
| Sudden onset. | Gradual onset. |
| Fever is high and regular. | Fever is not so high, and is irregular. |
| Ends by crisis between sixth and tenth day. | Ends by lysis, at no particular date. |
| Generally only one lung affected. | Generally both lungs affected. |
| The physical signs are distinct, and there is a large area of consolidation. | Physical signs indistinct, and the evidences of consolidation are indefinite. |
| Sputum is rusty. | Sputum is rather streaked with blood. |

In *pyemia* there will be a prolonged chill or several successive chills, profuse sweats with decided fall of temperature, oscillating temperature, embolic or metastatic abscesses, vomiting, and emaciation. These are not present in pneumonia.

3. In *mitral insufficiency* there is a blowing murmur, heard best near the apex, systolic, transmitted to left axilla and under left scapula; it modifies or replaces the first sound. In *aortic insufficiency* the murmur is soft and blowing, is heard best over the aortic area, is diastolic, is transmitted down the sternum, and modifies or replaces the second sound. The left ventricle is hypertrophied and the pulse is of a characteristic ("water-hammer") type.

*Compensation:* "The alteration in the systemic blood supply caused by the valvular defects of chronic endocardial inflammation are such that if continued the integrity of the body is threatened. To overcome the impaired functions of the valves and to maintain the general circulation the heart increases in size and strength (*compensatory hypertrophy*). The period in which this occurs is called the *period of compensation;* its duration is indefinite. It may be recognized by the physical signs of valvular disease without any symptoms of disturbed circulation. Anything which disturbs the equilibrium as it now exists, such as acute diseases and excessive work, leads to *ruptured compensation,* a condition attended by cyanosis, dyspnea, edema, gastric, hepatic, and renal disturbances, and often death." (*Hughes' Practice of Medicine.*)

*Treatment of broken compensation:* "Where compensation has failed, cardiac tonics are required, and of these digitalis stands first. It acts beneficially by slowing the action of the heart and prolonging its diastole, thus increasing the natural rest. It also increases the force of the cardiac beat. In addition it has a diuretic action and thus tends to relieve dropsy. . . . Sudden breakdowns of compensation call for complete rest and stimulation of the heart by ammonia or ammonium carbonate. Where the right heart is over-distended, strychnine hypodermically, along with a mercurial purge, and, if necessary, removal of blood by leeches over the liver or by bleeding from the arm, are required." (Wheeler and Jack's *Handbook.*)

4. UREMIA. The *symptoms* are especially referable to the nervous system, and include such premonitory signs as headache, vertigo, nausea, indistinct vision, drowsiness, constipation, scanty urine, which may contain albumin, etc. The uremic seizure may manifest itself by marked gastro-intestinal disturbances, convulsions, or coma with more or less rise of temperature, nocturnal dyspnea, Cheyne-Stokes breathing, vomiting, diarrhea, dry skin, scanty albuminous urine with casts, etc. *Treatment* should be directed toward elimination of the poisons. Croton oil (one drop) and olive oil (℥1) should be administered at once, and later elaterium (gr. ⅛), calomel (gr. 2), and compound jalap powder (gr. 20) should be prescribed. A hot bath (110° F.) or a hot vapor bath should be given to produce free diuresis. Chloral (31), nitrite of amyl, or chloroform may be needed to control the convulsions. The diet should be liquid, and the condition of the pulse will govern the use of sedatives or stimulants. (*Pocket Cyclopedia.*)

5. *Simple catarrhal jaundice* is caused by some undetermined infectious agent, extension of catarrh of the duodenum up the common bile-duct, and certain diseases, as pneumonia, typhoid fever, etc. The symptoms are nausea, vomiting, dull frontal headache, mental hebetude, jaundice, constipation, high-colored, scanty urine, slow and full pulse, and slight fever. The condition terminates favorably in 1 to 3 weeks. The treatment consists in rest in bed, liquid diet, and the administration of fractional doses of calomel (gr. ¼ every hour for 6 or 7 hours) followed by a saline purge if necessary. Later, constipation may be avoided by the use of the salines and mineral waters. Lavage, rectal irrigation, and blisters over the right hypochondrium may be employed. (*Pocket Cyclopedia.*)

*Obstructive jaundice* is caused by impaction of foreign bodies, pressure of tumors, inflammation of the ducts, or parasites. Symptoms are yellow skin and conjunctivæ, pruritus, sweating, discolored perspiration and saliva, boils, herpes, slow pulse, pale and gray colored feces, headache, vertigo, mental dulness and irritability. The jaundice is only a symptom, and treatment must be directed to the underlying cause.

6. In *follicular tonsillitis* the onset is more sudden; the temperature may be a little higher than that of diphtheria; there is no membrane, but the tonsils are red and swollen, and in the crypts are seen white cheesy spots or plugs which consist of broken-down epithelium, and are easily brushed away; Klebs-Loeffler bacilli are never found.

In *diphtheria* the onset is more gradual; the temperature rises to about 101° to 103° F.; the tonsils are not much enlarged; there is an exudate of a thick grayish membrane which is very adherent, is removed only with difficulty, and leaves a bleeding surface; this membrane soon reforms, and may be found on the fauces and pharynx as well as on the tonsils; in the exudate the Klebs-Loeffler bacilli may be found.

*Treatment of tonsillitis:* Calomel, and saline laxative; salicylates or aconite for the fever; potassium chlorate as a gargle; antiseptic spray or mouth wash.

*Treatment of diphtheria:* Administer antitoxin at once, in dose of from 2,000 to 8,000 units; isolate the patient; antiseptic solutions or Loeffler's solution may be used to swab out the throat and nose; tonics and supporting treatment are also indicated.

7. UNCINARIASIS. *Symptoms:* Anemia; pale and yellowish skin; lack of growth and development, both mental and physical; relaxed tissues; protruding abdomen; dropsy. *Diagnosis* is made by making a microscopical examination of the feces and finding therein the eggs of the hook worm. *Treatment:* Children should wear shoes; proper toilet facilities should be provided; a dose of calomel is given, on an empty stomach; this is followed by a dose of Epsom salt; after the bowels have been thoroughly emptied thymol in capsules is administered, dosage varying according to the age of the patient, children from 5 to 10 years of age taking 15 to 30 grains, and adults from 60 to 100 grains. On the day that the thymol is taken the patient is practically starved, except for a cup of coffee. The disease is not limited to children only, though they are by far the most frequent victims; exceptionally, adults may take the disease.

8. The *opsonic index* is the relative amount of opsonins in a serum, as compared with the normal standard. It is obtained by dividing the average number of bacteria taken up by a leucocyte under the influence of a given serum, by the average number taken up by a leucocyte under the influence of standard normal serum.

9. *Degrees of burns.*—Dupuytren's classification: *First degree,* reddening of the skin. *Second degree,* blistering. *Third degree,* destruction of the epidermis, Malpighian layer, and papillæ of the derma. The sensitive nerve terminals are exposed; consequently this is the most painful degree. The sweat and sebaceous glands and hair follicles are not destroyed, and from these epithelium spreads in healing, so that repair is rapid, and the scar is not a contracting one. *Fourth degree:* the whole thickness of skin and part of the subcutaneous tissues are destroyed. *Fifth degree:* the muscles are injured. *Sixth degree:* the whole limb is charred.

*Treatment.*—General: If carbonic-oxide-poisoning is present, artificial respiration and administration of oxygen. For shock, opium and stimulants. Local: For burns of the first degree, powder with boracic acid. Puncture blisters, and cover the part with an antiseptic dressing.

Burns of deeper degrees than the second must be made aseptic with 1 in 1,000 bichloride of mercury. Antiseptic gauze dressings should then be used. Picric acid (20 grains to 1 ounce of water) is used as a dressing. The continuous bath may be used. If the burn be of any size it should be skin-grafted, as the scars of burns contract very much. (*Aids to Surgery.*)

*Complications of burns:* Asphyxia, shock, syncope, ulceration of the duodenum, exhaustion, and toxemia.

10. See SURGERY, question 10.

## Therapeutic Hints.

**Inhalations in Chronic Bronchitis.**—M. Hirtz, in his "Therapeutics of Respiratory Diseases," recommends the following as a useful remedy in cases of chronic bronchitis:

℞ Beechwood Creosote, 25 grams.
Tincture of Benzoin, 20 grams.
Eucalyptol, 10 grams.
Thymol, 20 grams.
Gomenol, 20 grams.
Alcohol, 200 grams.

Two tablespoonfuls of this mixture are to be added to one quart of water which is kept boiling from time to time.—*La Presse Médicale.*

**The Prescribing of Cannabis Indica.**—Plique recommends as an effective sedative a combination of the fatty extract of cannabis indica with lupulin and the extract of humulus as follows:

℞ Fatty Extract of Cannabis Indica, 0.05 gram.
Lupulin.
Extract of Humulus, of each, 0.50 gram.

To be divided into ten pills.

The following potion is recommended by Berthier:

℞ Alcoholic Extract of Cannabis Indica, 0.20 grams.
Weak Infusion of Coffee, 60.00 grams.
Sugar, q.s.

The coffee is of value in diminishing the torpor. The fatty extract is more active, toxic, and certain in its effects than the alcoholic extract.—*Bulletin Générale de Thérapeutique.*

**Treatment of Gonorrhea.**—J. E. R. McDonagh states that the following prescription is occasionally of value in the treatment of gonorrhea:

℞ Copaibæ, ♏xv.
Pulv. Cubebæ, grs. xxx.
Potass. Iodid. (increasing doses), grs. x.
Spir. Ether. Nitrosi, ♏xv.
Mucilag. Acaciæ, ʒj.
Infus. Taraxaci vel Buchu, ad ʒj.

When this mixture is given there should be ordered injections twice daily of a 1 in 4-8 solution of hydrogen dioxide. The latter liberates the iodine derived from the potassium iodide. The iodine has a powerful destructive influence on the gonococcus. —*The Practitioner.*

**Local Applications in Pruritus.**—Darier has found the following lotion to be highly effective:

℞ Lanolin, 10 grams.
Vaseline, 20 grams.
Cherry Laurel Water,
Rose Water,
Orange Flower Water, āā, 10 grams.

Guéneau de Mussy combines potassium bromide with camphor as follows:

℞ Potassium Bromide, 2 grams.
Camphor, 0.20 gram.
Simple Cerate, 20 grams.

Bulkley finds that the local application of chloral is particularly of value in cases of insomnia due to pruritus. His formula is as follows:

℞ Camphor,
Chloral Hydrate, of each, 4 grams.
Unguentum Aquæ Rosæ, 30 grams.

Hebra's prescription is the following:

℞ Washed Sulphur, 18 grams.
Precipitated Chalk, 12 grams.
Sesame Oil, 18 grams.
Green Soap,
Lard, of each, 50 grams.

—*Le Bulletin Médical.*

## Miscellany.

**The Growth of a Legend.**—"X" relates that he "has recently been watching, with much interest, the circulation through the weekly papers, of a story anent the artist Whistler and Sir Morell Mackenzie, which, curiously enough, starting in Paris, has now reached the American medical Journals and seems embarked on a long and active career. Briefly, it is this:—Whistler's pet poodle being very ill, Sir Morell Mackenzie was sent for in hot haste. Indignant at having been summoned to see a dog, he, nevertheless, pocketed his dignity, and prescribed, *secundum artem.* Whistler, having thanked the 'eminent surgeon' profusely, begged to know the fee. Sir Morell, turning away, said pleasantly, 'Oh! My house wants painting. Will you see to it?' Now Sir Morell Mackenzie was, without doubt, an accomplished laryngologist; but why Whistler—whose brother, by-the-bye, was almost equally celebrated in the same department of medicine—should have desired the services of a laryngoloist for his poodle, heaven only knows. Mr. Ben Trovato, the eminent raconteur, seems for the moment at fault. Still, the natural history of such legends as this leads us to suppose that the story of the laryngologist and the poodle will continue to circulate, till after having served its day it 'falls on sleep,' later to be revived by the journalists of the next generation about some heroes of to-day.

"Many years ago there was related in that excellent, even if mid-Victorian periodical, *The Leisure Hour,* a similar story; but this time concerning Nélaton and Meisonnier. Some time during the early days of the Second Empire, Nélaton was urgently summoned to the painter's villa in the *banlieue de Paris.* After some time had been spent in the way of sumptuous entertainment, Nélaton, a little impatiently, begged to be introduced to the sufferer. Whereupon two gorgeous flunkeys entered the room bearing on a cushion a little dog with a broken limb, and the master fell on his knees entreating the surgeon's forgiveness and aid. Nélaton addressed himself to the case, and set the limb; he was departing, when Meisonnier desired to know, as Portia would have said, how he might gratify the gentleman, for, in his mind, he was much bound to him. The story goes that Nélaton then declared the door of his '*cabinet de consultation*' to need painting, and hoped that the artist would restore it. Meisonnier seized the occasion, we are told, of the surgeon's temporary absence from Paris, to produce, on each panel, a veritable *tour de force.*

"Now this is a more exquisite tale than the other. But the germ of both may be traced in the episode of Radcliffe and Kneller, as related by the veracious Pittis. Radcliffe and Kneller lived near each other in Bow street; their gardens were separated by a wall. Radcliffe, for the better entertainment of his friends, begged the privilege of entrance to Kneller's plaisaunce, through a door which he desired to make in the wall. The painter, with accustomed grace, gave his assent, but, the privilege being abused by the doctor's servants, had thereafter courteously to hint that if the grievance recurred, the door must be bricked up. Whereupon the choleric doctor sent a message to say that Sir Godfrey might do what he liked to the door, so long as he did not paint it. 'Did my very good friend, Dr. Radcliffe, say so?' cried Sir Godfrey. 'Go back to him and after presenting my service to him, tell him that I can take anything from him but his physic!'"—*The Universal Medical Record.*

### JAN PALFYN.

BY JOHN BETHUNE STEIN, M.D.,

NEW YORK CITY.

THE records of Courtrai, Belgium, show that the subject of our narrative, the son of Egide Palfyn and Marguerite de Rore, was born on the 28th of November, 1650. This city, in recognition of his services to mankind and science, has named a street in his honor and erected a statue to his memory.

The father of Jan Palfyn was a surgeon-barber, a profession which at that time was still in its infancy. It was neither lucrative nor considered honorable and its practitioners were banished to the lowest order of society.

As Palfyn grew older he participated more and more in his father's knowledge of the profession of surgeon-barber; and incomplete as were these first notions of medicine which he obtained, they nevertheless were of advantage in that they stimulated him to deeper studies.

FIG. 1.—Jan Palfyn, 1650-1730.

Perhaps Palfyn detected that the deceptive, uncertain and fumbling character of the art, which his father practised, occasioned grave fear and anxiety on his father's part, for the patients who consulted him; or perhaps Palfyn was precocious and by inquisitive and naïve but sensible and perplexing questions, drew from his father belated reflections on the lack of foundation possessed by him, regarding the art which he practised.

Palfyn recognized the fact that in order to avoid the fear and anxiety experienced by his father, he must obtain a greater knowledge of anatomy. All his energy was directed to this end and his inclination towards and enthusiasm for anatomy remained ever the same as it was when he first started in quest of this subject. In proof of this we find in the preface of one of his books the following: *"I have always loved the science of anatomy beyond measure: I have applied myself to it with an insatiable passion; having in view the aim to be able to practise surgery with the greatest security."*

At the age of sixteen he had acquired all his father could teach him, and had read all the books which were at his disposal. These books served little purpose other than to improve his knowledge of Flemish which the scientific world then refused to use.

To his chagrin the only treatises on anatomy were written in Latin, a language foreign to him and a knowledge of which he could not easily obtain. He found himself face to face with almost insurmountable obstacles, without resources, counsel or help.

During the next four years having acquired at great hardship a knowledge of Latin and having interested certain benefactors to open the way to him for study, he conceived the project of translating into a popular language the ideas of those Latin authors which he valued so highly that others in the same position as he formerly was might avail themselves of them.

He pushed the scientific impatience up to the point of a will—as Vesalius did—to scrutinize the secrets of nature. His earnestness led him to rob the cemeteries.

Palfyn lived at a time when the development of science encountered—but fortunately in vain—the greatest obstacles, religious fanaticism, immutability of dogmas, the social constitution, the prerogatives of jealous castes and finally the repudiation of a modern native language as a scientific one. Harkening only to his passion for investigation, and feeling that he ought to affront these prejudices, which, in his eyes, could only prevent the development of the public good, for he considered all else subversive, he made up his mind that for the obtaining of anatomical and surgical knowledge he was obliged to dissect cadavers; and therefore conformed his conduct to this end. Great prejudices against dissection existed at Courtrai. It was extremely difficult for him to obtain cadavers although the plague still existed in Flanders. He was detected in a cemetery opening a tomb, was accused of sacrilege, and in order to escape the penalty of the law sought refuge in Ghent.[1]

This change obtained for him resources and conditions which favored his anatomical and surgical studies. He became the apprentice of a surgeon in Ghent who was connected with the medical school and who obtained for him the opportunity to attend lectures and the privilege to dissect. Here he became familiar not only with the names of the scientific centers of Europe, but also with those of the prominent medical men of the day and their works. As a result, after remaining three or four years in Ghent, studying and becoming familiar with the French language, which he considered indispensable for appreciating medicine, he left for Paris.

At Paris he met and worked with two of the most celebrated anatomists and surgeons of that period, Jean Devaux and Pierre Dionis.[2] Here "his knowledge became so extensive and his judgment was so exact that a large number of medical practitioners consulted him regarding the diagnosis and treatment of their patients."

From their first meeting in 1674, when he made his first trip to Paris, a durable friendship existed between Palfyn and Devaux.

Attachment to his country, and a desire to render an account of his work at Paris to those who had helped him at Ghent, induced him to return home, where he was received with particular distinction, and being convinced that he could not give up his time to an art which was still so unscientific, he aspired to the career of teacher and writer and determined not only to investigate for himself but also to collect and group the scattered scientific facts then being, and theretofore demonstrated by the various workers in different countries.

After remaining a short time at Ghent he returned to his native city, Courtrai, where protectors and friends had obtained pardon for his early offense and made residence for him possible; but he always remained under suspicion, and we shall see how eleven years later for analogous reasons he

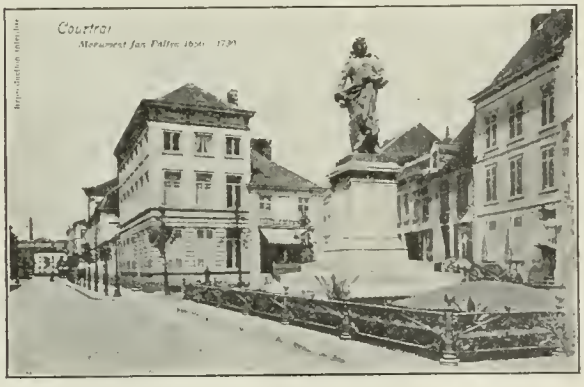

Fig. 2.—Monument to Jan Palfyn at Courtrai.

was again obliged to leave Courtrai and to establish himself at Ypres. At Courtrai, November 7, 1679, he married Marguerite Wallaert. Five children were the result of this union.

The departure of Palfyn for Ypres in 1686 or 1687 is undoubtedly connected with a quarrel between him and the Royal College of Medicine at Courtrai. The directors of this institution had in vain called Palfyn before them on four separate occasions, viz.: December 22, 1683: January 5, 1684; January 12, 1684, and again later when he was fined six florins for his "inobedience in refusing to explain satisfactorily a skeleton found in his possession."

Regarding the skeleton in question, the documents of the Royal College are not explicit.[3] We do not know whether Palfyn had again desecrated a cemetery or whether the authorities objected to his retaining human bones—perhaps otherwise obtained—at his home, where it was necessary for him to study them in the preparation of a work on osteology.

He fought with all his might the affectations raised by the narrow fanaticism of the people of his time, and he preferred to expatriate himself, rather than sacrifice his convictions, viz.: that for the good of humanity, for the rationalistic practice of surgery, it was the duty of the professional scientists to base the science on a thorough knowledge of anatomy.

He withstood for three years mortifications without number, by which he was overwhelmed, as he did not leave Courtrai for Ypres till 1686 or 1687. Here his wife died in 1691. He then spent two years in Paris, 1692-1693. His second wife, Marie de Bois, bore him a son at Ypres in 1694.

Palfyn in his writings tells of the years he spent studying at Courtrai and Ypres, how he made repeated trips into foreign countries, to learn scientific facts in order to assemble the material for his work, which was to consist of a method of teaching surgery based upon the then recently investigated knowledge of anatomy.

Some of the contemporaries of Palfyn resented the annihilation of the art of surgery, due, as Antoine Petit,[4] Regent of the Faculty of Medicine in Paris, said, in a lecture at the opening of a course in surgery November 27, 1757, "partly to the heedlessness and inconsideration of physicians who referred surgical cases to their underlings (among whom were the barbers) and to a fault of the surgical writings of the time in neglecting their natural function to pursue strange objects."

This debasement of surgery (for surgery at this time was separated from medicine, its guide and natural support), had caused much mischief. The barbers had been the means of making surgery the lowest sort of a trade. They were extremely ignorant and came from the dregs of society and practised a brazen charlatanism.

Was it astonishing that operations were performed without knowledge and necessity and that violent proceedings multiplied without reason or aim?

Palfyn was compelled not only to denounce the turpitude of the pseudo-surgeons and to bring before the public the unfortunate consequences of their culpable incapacity, but he also had to fill the places of those whom he discredited with truly learned men which he could only accomplish by teaching and making anatomical knowledge popular through his writings in the vulgar tongue.

At this time all Europe was aroused by the birth of microscopic anatomy and physiology, and if Palfyn's name cannot be placed among those of the illustrious men of this period, it should certainly follow them closely, for he was the first who, by means of a treatise on surgical anatomy, written in Flemish, supported by a judicious appreciation the ideas and discoveries of these men.

He placed himself en rapport with the greater part of those who made a study of medicine. He journeyed in England, France, Germany and Holland, and frequented the most celebrated schools of medicine, attaching himself more especially to hospitals and the great masters at Paris, Leyden, Louvain and Utrecht. He performed a giant's work in tracking the newer innovations and discoveries, and he showed an aptitude, not common, for appropriating facts which were both very new and abstract. Nothing escaped his attention, and he was recognized as one of the best informed medical personages of his time. An example in his writings serves to prove how he attached himself to the progress of medicine and how investigators were eager to communicate their recent ideas and discoveries to him.

On page 257 of his Treatise on Surgical Anatomy he says: "One cannot believe with what rapidity the blood circulates in the small vessels unless one con-

vinces himself by examining it either in the eel, frog, tortoise or lamprey. I have had the pleasure to see it admirably well in the tail of an eel by means of the microscope of the celebrated Leeuwenhoek at Delft in Holland, and since then at Paris M. Verdier, surgeon and demonstrator of anatomy, has also

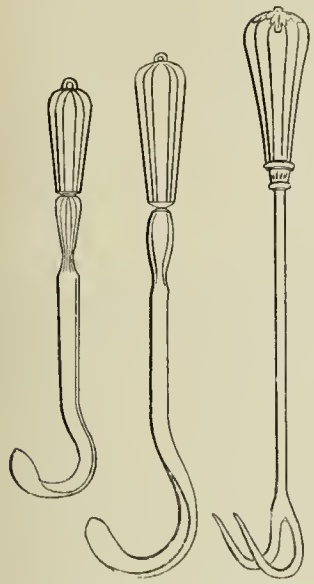

Fig. 3.—Sharp and blunt hooks. (From Ambroise Paré.)

Fig. 4.—One blade of Palfyn's forceps. (From Heister.)

shown me by means of the microscope the lymph circulating in the vessels of the mesentary of the frog."

Palfyn informs us in his writings how he spent nineteen years of his life, from 1676 to 1695, gathering together scientific data, which were scattered throughout Europe, and how he desired to coordinate these and thus make others feel the same respect for anatomy, physiology, and surgery as he did. He was then forty-six years old and had arranged all the material for his Treatise on Osteology, his Surgical Anatomy, and his Treatise on Surgery, when Ghent attracted him, and he left Ypres and established himself among his old protectors and friends at Ghent in 1695.

Here he practised surgery, passed his most prosperous years, achieved the climax of his fame, and his first book (1701) appeared. This work, as well as his other works, excepting one, was written in Flemish, but before publishing he submitted it to Devaux at Paris and Verheyen at Louvain, and on June 5, 1701, to the Medical Faculty at the University of Louvain, at that time one of the most famous in the world. He journeyed to Louvain with his manuscript and bones in order to prove that there was a communication between the cavity of the skull and the face, by means of the frontal, sphenoidal and maxillary bones. This was an important and debated question. An exact knowledge of the function of the orifices and canals of the cranium decided a delicate problem, viz., "whether humors were formed in the brain which were obliged to free themselves by natural openings." Palfyn maintained that these openings in the base of the cranium lodge vessels and nerves and that the structure of the mucous membrane of the nose was the same as other mucous membranes, where scattered glands were found, which secreted fluids to lubricate their surfaces.

Palfyn satisfied the Faculty who confirmed his proof in writing, with the academic seal attached, which latter he was permitted to use. This paper was signed by Philippe Verheyen, L. Peeters and J. Somers, under date of June 9, 1701. Palfyn's first work saw the light at Ghent in 1701 and was a volume of 418 pages.[5] The following is a translation of the title: *A New Osteology. The true and precise description of the bones from the human body, all taken from his own experience and enlightened by the newest discoveries in anatomy. By Jan Palfyn at Ghent. Published by Van Danckaert,* 1701. A second edition appeared at Leyden, 1702. It was translated into German and appeared in 1730 at Breslau, and Palfyn translated it into French, publishing it in Paris, in 1731. An edition appeared in Amsterdam, 1758.

The work was not simply a description of the bones, but a complete exposé of the then acquired knowledge of their nature, structure, and function, including their articulations and the diseases involving them. This osteology was remarkably clear and precise. He proved many of his statements by striking clinical examples. The osteology of the head is indebted to his spirit of observation and rigorous investigations. The success of the work was complete, and Palfyn was designated the "Celebrated Anatomist of Ghent" by the savants of France, Holland, England, and Germany.

Having taken frequent trips throughout Europe, in order to obtain the latest scientific knowledge, he came to Leyden to meet Boerhaave, and before meeting this great physician he became acquainted with some of his pupils, and inquired if there was any new work upon osteology. "We study with eagerness," they answered, "the Treatise on Anatomy by Palfyn; it has charmed our master so much that he has read it three times." "Well," said the modest traveler, "go and tell him Jan Palfyn waits upon him." Boerhaave had no sooner heard his name pronounced than he rose and embraced him with the cordial simplicity of the Hollanders. "It is long since I have desired to see you; your works please me greatly and I approved of all your opinions." Boerhaave, however, was unsuccessful in attaching Palfyn to the University of Leyden.

Fig. 5.—Church of Saint Jacques at Ghent.

But Palfyn's work was not in Latin, and this combined with the manner in which his Treatise on Surgical Anatomy attacked the inaptitude and incapacity of the surgeons of his time made for him many enemies.

The following, which is an almost literal translation from the Flemish of the dedication of his work on osteology, may be of interest:

"Who is there among the Christians who does not know that after the fall of Adam men were subjected to so many diseases that it is a special favor from the Everlasting Goodness out of Which everything is, through Whom everything is, and in Whom everything is, that He Who to some of the human race gives light to recognize illnesses and accidents, gives to them power the same to drive away and protect men from the same. To the Almighty Architect of Heaven and Earth, Who is the beginning and end of all things, the Supreme Physician of Soul and Body to Whom alone belong esteem, honor and glory."

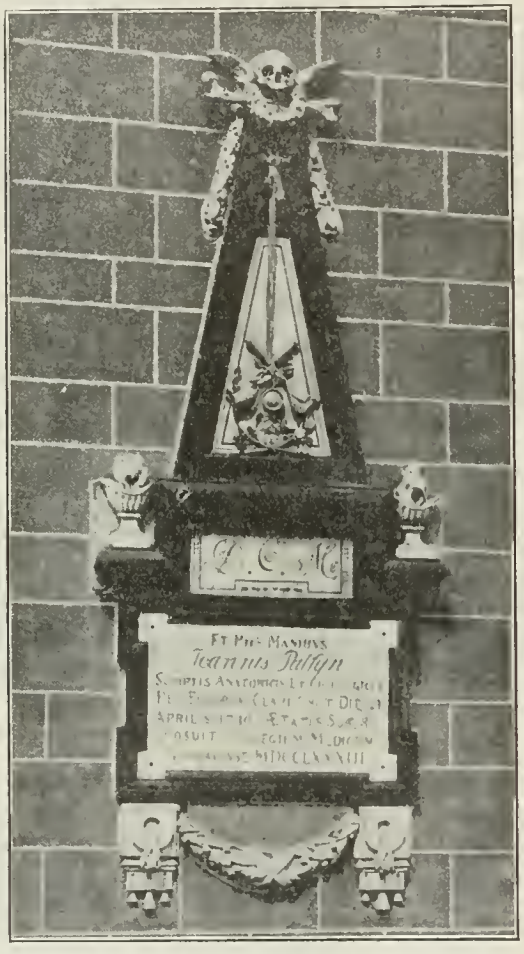

Fig. 6.—Cenotaph of Jan Palfyn in the Church of Saint Jacques at Ghent.

On account of his great reputation as an anatomist, the authorities of Ghent made him Professor of Anatomy.

de Mersseman[2] states:

"In April, 1703, twins were born united at the lower part of their bodies which created such a stir that Palfyn was selected to dissect them (instead of their own so-called pensionary anatomist) before the magistrate, the directors of the college of medicine and the principal practitioners. A month later another monster was born at Ghent, which he also dissected, in which an imperforate anus and vagina, together with a double uterus were found, and he was requested to make a report on his findings. The results of these dissections led him to publish a work dealing with the circulation of the blood in the fœtus. It was written in Flemish published at Ghent in 1703, and in Leyden 1708. The following is a translation of the title:[6]

*"An anatomical description touching on the wonderful state of the outside and inside parts of two children, which were monstrously joined to each other in the trunk of the body, born at Ghent, April 28, 1703; to which is added the strange constitution of some parts from another child, one of twins, not less wonderful than the above-mentioned case, born, in the same city May 27, 1703. Thereby are shown the unusual condition found in unborn children and the difference in the circulation of the blood in them and in older people. Never before this has this been brought to light in the Netherlands."*

As this work was so well received, and as the practices were so crude and inconsiderate in cases of maternal and fetal distociæ, the causes being but little known and the child frequently injured and the mother lacerated, he wrote upon the anatomy of the female organs of generation and that of monsters.

This work,[7] written in French and published at Leyden (1708), passed through four successive editions. In 1724 it was translated into Flemish.

The character of his writings, his general ability in his profession, and the fact that he was a distinguished anatomist and able surgeon who had exerted much influence upon the teaching and practice of surgery, caused the authorities at Ghent in 1708 to appoint him Professor of Surgery in their School of Surgery. J. de Mersseman says: "Although he was at this time nearly sixty years of age, his energy and enthusiasm had not abated and his teachings were both clear and practical. His continued correspondence with the greatest savants of the century coupled with the knowledge he had obtained by his frequent journeys throughout Europe permitted him to give his students all the surgical knowledge which was available at that period."

In the preface of the Flemish edition of his surgical anatomy printed in 1718 Palfyn indicates how he had devoted his life to medicine; scoffs at the ignorance of his time, speaks of the exigency of surgical teaching and says the aim of his life had been to have such pupils as would be worthy to represent *"the most necessary art of all,"* which had been for a very long time misunderstood. Palfyn expresses himself as follows, in the preface of this book: "Speaking of my osteology to a celebrated surgeon (*) in Paris, he advised me to write a treatise on anatomy for young surgeons, which, by instructing them in the structure of each part, would cause them to observe that which they must do and avoid, in operating, in order to maintain the organs or to re-establish them in their integrity and to preserve them from the harm that poor work would do them. Such a work was desired long since, but no one had taken the trouble to write it."

His "Surgical Anatomy of the Human Body" was first published[8] in 1710 and passed through numerous editions, being translated into French, German, and Italian, and, although Velpeau, in 1825, said it was "decorated with an empty title," he completely retracted this statement in the introduction, page 8 of the third edition of his own work on surgical anatomy,[9] Brussels (1834), where the following passage is seen: "Palfyn has the glory to have introduced into science the title *'Surgical Anatomy.'*"

Palfyn's "Surgical Anatomy" was followed by a "Treatise on Surgery" (1710), which was also written in Flemish[10] and translated into German in 1717 (Frankfort and Leipzig).

Here is the title of Palfyn's Treatise on Surgery: *"A precise dissertation of the principal works of surgery in the hard parts as well as in the soft of the human body—Brought to light by Jan Palfyn, sworn surgeon, anatomist and lecturer on surgery at Ghent. Being a work very useful to all medical men and surgeons. In two parts,* 506 pages, with illustrations. At Leyden, Christianus Vermey, 1710."

In the preface of the French edition of his Treatise on Surgery, published in 1726, when Palfyn was seventy-six years old, he says:

"I have always contemplated translating this book into French in consideration of the young surgeons of that nation, who are scattered not only in our provinces, but in Holland, Prussia, and different parts of Germany and the northern countries, the object being to make a slight restitution for the good teaching I have obtained in the schools of Paris in my youth and of which I have tried to make still better usage in my maturer years."

J. L. Petit[11] is quoted as saying of Palfyn's Treatise on Surgery that: "The truths concerning anatomy and surgery scattered in the best books, together with Palfyn's own discoveries as collected and set forth by him form a perfect whole, serving as a faithful guide in the practice of surgical operations disentangling the true from the false and sparing the trouble of reading the works of a great number of authors." In the Treatise on Surgical Operations, which deserves a high place in the history of surgery, Palfyn describing clearly, precisely and in detail the different surgical operations which were undertaken at this time, explains the procedures, necessity and applications of operations. In the introduction he gives the following precept, that in the need for and carrying out of an operation the questions in the following verse must be answered:

*Quis, quid, ubi, quibus auxiliis, cur, quomodo, quando?*

Palfyn discouraged a blind faith in the acts of others and taught the necessity of regarding acts in the light of science and reason and thus it was he justified the innovations which he had introduced in his book, *e.g.* suture of wounds of the intestines, a new explanation of the cause of hernia and strangulated hernia and the cure of the latter by operation. The author was "convinced that the edges of a wound of the intestine would not unite, but would adhere to the tissue of the skin or peritoneum." He proscribed continuous sutures for wounds of the intestines "as they irritated the parts by the multiplicity of punctures, and diminished the caliber of the canal, interfering with the circulation in the intestine and thus causing death." He discusses paracentesis, an operation for empyema, and the treatment of cancer of the breast.

According to Palfyn it was very difficult to recognize cancer in its early stage, when he said it was curable. An operation of his for cancer consisted in "cutting the skin in a cross, extirpating the 'scirrhus' from below upwards, so as not to be hindered by the bleeding." He advised cauterizing all the little tubercles immediately situated under the skin. In ulcerated cancer of the breast he amputated the entire breast; performing Bidloo's operation, which in Jourdan's[12] Histoire de la médecine, Paris, 1815, translated from the German of Kurt Sprengel, 1794-1795-1796, vol. 8, page 437, is described as follows:

"He placed a pad in the axilla of the affected side, then placed the forearm under the patient's back, grasped the breast and tied it firmly at the base with a ligature. He then plunged a stilet either transversely through or in front of the pectoralis major muscle, raised the ligature and cut the breast from above downwards with a sharp razor. The hemorrhage, which was slight, as only vessels of small caliber were divided, was arrested with lint, gypsum, and burnt calf's liver."

For the relief of strangulated hernia he advised operating and invented a bistoury for this purpose.

Fig. 7.—Monument to Jan Palfyn in the Church of Saint Jacques at Ghent, designed by Charles Van Poucke, Cura Collegii Medici Hujus Urbis Aere Munificentia—Plurium Bonarum Artium Remuneratorum Erectum Anno. 1784.

Haller,[13] in speaking of this instrument, says: "Cultrum herniarium, similem illi Ledrani."

His works met with the esteem of such men as Winslow, Geoffrey, Carron, Duverney, Mery, Petit, Morand, Devaux, Heister, Haller, Peeters, Somers, Verheyen, Ruysch, and in the introduction of his Surgical Anatomy, published in 1726, the following statement is attributed to Albinus and Boerhaave: "Before him no author had so methodically and clearly, with such meaning and intelligence, combined anatomy with surgery."

Palfyn having spent much time studying the diseases of the eye, especially cataract, was about to publish a work on the cause and treatment of cataract, when a treatise on the diseases of the eye by Jean Antoine[14] (1707) appeared, followed by Bris-

seau's[15] work on "The Nature of Cataract," Paris, 1706. Palfyn translated Antoine's work into Flemish, supplementing it by additions of his own. This work[16] ("The Surgical and Medical Treatment of Diseases of the Eye") appeared at Leyden in 1714 and embraced the entire knowledge then extant of the anatomy, physiology, pathology, and treatment of the eye.

It is generally known that the forceps, consisting of two non-separable parts, were probably used by the ancients, and the claims of Peter Chamberlen and others mentioned in this article to the invention or reinvention of the forceps are familiar to us, but the reasons why credit for the invention should be given Palfyn have not been sufficiently recognized.

The lamentable manner in which obstetrics was practised at this time did not escape Palfyn's attention as is attested by his writings. In his work on osteology he described with particular care the bones of the pelvis, making a differential study of them in the sexes and discussing the mooted question whether the pelvic bones separated during parturition, said with irony that "the midwives questioned upon this point had decided the question affirmatively."

In his "Treatise on Surgical Anatomy" the following passages, of which a literal translation is given, indicate his familiarity with obstetrical practice.

Page 208. "Surgery is of no great help in natural delivery, that is to say, when the infant is at term, as the child and mother are well arranged to each other and as the infant presents itself in a favorable situation, that is to say, that it presents the head first, or the feet first, as obstetricians are not in accord which of these two situations they consider the most favorable position. But when the delivery is contrary to nature or because the infant presents itself in positions the most bizarre or because it is necessary to deliver a woman in an unnatural manner (de force), or because it is accompanied by extraordinary casualties, when nature can do nothing by herself, the delivery which depends entirely upon art demands upon the part of the surgeon a great dexterity, as these are the operations the most intricate and difficult."

Page 219. "I have often observed in making an incision in the uterus in the Cæsarian operation that its thickness was at least the thickness of a finger in a woman seven to eight months pregnant."

Goffin[11] says of Palfyn that having seen the operation of cesarean section and the operation with the so-called sharp hook result disastrously to both the child and the mother, he gave much thought to this subject, and finally decided that if the head of the child could be seized by an instrument in the same way as by the palms of both hands, the life of the child would be saved. This simple conception of Palfyn's changed the face of obstetrics "and by many he is considered the inventor of the forceps."

On page 307 of the first part of his Treatise on Surgery Palfyn states that: "The doctor is often the cause of the death of the child by inflicting a head wound, demonstrated in a case which I witnessed not long ago, where the fœtus, apparently dead, was with the aid of an iron hook inserted in the occiput, extracted. It was alive but lived only one day. But what shall I say? There are many difficulties in medicine which cannot be overcome by the wisest physicians."

He cites another case on page 388 of the same work. "When I came back from Paris to the city of Ypres I saw a child three months old, of a French drum-major, which being born with the arm first, had its arm cut off at the elbow by the doctor, who thought the child dead, but after birth found it living."

According to Herman Tronckey[17] (City-Operator, Obstetrician, Cutter for Hernia and Stone at Amersfoort, in a Treatise on Obstetrical Practice, Amsterdam, 1728) Palfyn, on one of his visits to Boerhaave, made a drawing of a blunt hook, which he said, could reach higher in the genital tract than the hand. And Boerhaave replied: "It would be better to forge horseshoes than the 'Mains.' Recollect, my friend, that the inventor is the finder of the beggar's purse."

The instrument, so crudely drawn, subsequently became known as "les mains de fer" or "tire-tête" of Palfyn.

The following are translations of some of the passages concerning Palfyn in the work of Antoine Reiss[18] of the University of Strasburg, 1816.

"Obstetricians seem to have made the greatest progress since learning how to deliver the fœtus by the feet and the invention of instruments more convenient in extracting it by pieces in cases of absolute necessity. They early recognized how insufficient and ineffective were the means at their disposal. The wretched example of infants delivered living, but wounded and murdered by sharp instruments, led to means to deliver the fœtus by the head without wounding it. Palfyn presented to the Royal Academy of Science of Paris in 1721 an instrument with which he could, as with artificial hands, help the delivery of the head.

It seemed that nothing better could be desired. He did not wish to make his instrument known to the public before this society of savants had accepted it.

The instrument of Palfyn was first known as the tire-tête or mains de fer of Palfyn. The tire-tête of Palfyn was inconvenient in that each branch was a separate instrument, and each of the two branches was manipulated by one hand. The result was that the head of the fetus could not so forcibly or effectively be handled by the tire-tête as if the two instruments were but two branches of one instrument. But it is this defect of the tire-tête of Palfyn which proves its origin and which authorizes us to award the honor of this invention to this zealous and disinterested surgeon."

Ignace Rist,[19] quoting the historical part of a work by Mulder, a Dutch obstetrician, which was translated into German by Schlegel in 1798, says, regarding the origin of the forceps:

"If we refuse the credit of the invention of the forceps to Rueff,[21] a surgeon of Zurich, Switzerland, at least we cannot deny that he was the first obstetrician who conceived the happy idea of delivering with pincers a living child from the pelvis of the mother. His forceps are not furnished with the murderous teeth destined to crush the head of the fœtus and we can exert a pressure more or less strong with this instrument. After Rueff, the first who merits citation is unquestionably Palfyn. He directed the attention of a learned society to his invention. The spoons of his forceps adapt themselves well to the head of the fœtus and the branches are to be introduced separately."

"Jacques Rueff,[20] in his work, De Conceptu et Generatione Hominis, 1554, gives a description and

picture of a pair of flat pincers by which the head of a dead fœtus can be extracted without tearing it." (Goffin.[11]) But Broeckx[21] says that in neither France, Germany, Holland, nor Belgium was there a forceps known other than that of Palfyn before 1721.

In connection with their claims to earlier invention and especially the claim of Chamberlen referred to later, Mauriceau's experience is interesting.

Mauriceau[22] cites the case of a woman 38 years old, a primipara, in labor for eight days, the membranes ruptured the first day, without any dilatation of the cervix and the child was dead four days, he "feared to do a Cæsarian section, as it is always fatal for the mother." He said "Chamberlen attempted to deliver her and worked for three hours over her, only stopping to take breath."

The woman died and at the autopsy Mauriceau found the uterus torn and pierced in many directions by the instruments which Chamberlen used. "Chamberlen," Mauriceau says, "had come to Paris and had been there six months in the hope of making his fortune, proclaiming that he had a secret for accouchements of this character, and has offered to sell the secret to the first physician to the King for 10,000 escus."

Mauriceau adds: "The extraordinary difficulty which was encountered on this accouchement has made me invent an instrument which is easier and surer than the hooks."

It is evident that Chamberlen did not use the forceps in this case or Mauriceau would have spoken of them. Mauriceau gives a picture of his own instrument in his work (1694). It was a blunt-hook similar to that seen in the work of Paré and which he recommends for extracting the head of a fœtus remaining in the uterus.

Rist[19] cites the view of Levret as follows:

"One sees in Ambroise Paré[23] (De la Génération, liv. 18, ch. 33) a blunt-hook in the form of a spoon. Levret thinks that Palfyn obtained the idea of his tire-tête from this instrument. However, the hook of Paré can be applied to only the forehead or occiput, but the superior end of the instrument of Palfyn is less curved, larger and adapts itself to the sides of the head. Many surgeons wished to appropriate the credit for the invention, among others Gilles Le Doux, a surgeon of Ypres, but the honor of it belongs to Palfyn."

Levret,[24] 1747, states: "It is about twenty-five years ago that Palfyn, a surgeon at Ghent and Demonstrator of Anatomy in that city, came to Paris to publish his anatomy. He presented at this time to the Academy of Sciences an instrument to draw by the head infants locked in passage. He received the commendation as being the inventor of it. But Gilles Le Doux, surgeon at the city of Ypres, objects, saying that he invented it."

Levret answers an anonymous critic in the *Journal de Savants*, August, 1749, thus: "Heister accords to the forceps the name of Palfyn."

At first the forceps were not generally used, probably, because obstetrics was confined to the ignorant hands of sage-femmes (midwives) who, as Mauriceau[22] says, "were sage only in name."

The conditions making the use of the forceps unpopular when first invented are expressed by Reiss[18] as follows:

"The success obtained by the forceps could not be other than fortuitous. The injuries and inflammations of the sexual organs were at first so often the sequence of the operation that it was impossible to form a favorable idea of the utility and harmlessness of this instrument when properly applied. The axis of the pelvis was not then exactly determined; the direction that one must give the instrument when introducing and extracting it was not then exactly known; the blades did not have a curve conforming to that of the cavity of the pelvis, their introduction presented much difficulty; the fourchette especially was often maltreated when the fœtus was extracted; the mechanism of delivery, the relation of the head of the child to the pelvis, the signs indicating the position of the head were unknown: so it was that the delivery of the fœtus by means of an instrument was done at hazard and not in a proper way."

The invention of Palfyn and the new and ingenious idea to seize the head by means of an instrument which could not injure it did not meet with popular favor. However, convinced of the utility and efficacy of his invention, Palfyn had many of them constructed and presented them to the members of the Royal Academy of Sciences at Paris and to anyone else who desired to use them. Laurent Heister,[25] one of the most celebrated surgeons of his time, who had journeyed in Holland, England, and in Belgium, where he met Palfyn, received one of these instruments and speaks as follows:

"Ita mihi relatum est ab amico, qui haec ferramenta mecum communicavit, nam Palfinus ipse hac de re nihil, quod scio, litteris prodidet." This writer gives in his work a design of the instrument and names it after Palfyn.

"Hardly had he made known his instrument than many voices were raised to claim the priority, Chapman and Chamberlen in England and Le Doux in Ypres pretending to have invented the tire-tête of Palfyn," writes Broeckx.[21]

Doubtless the idea germinated in the minds of many surgeons at the same time to terminate difficult labor, but they were guided by a culpable egotism and sordid interest and guarded the secret of their invention. They took the greatest precautions and would not operate with their instruments before anyone who could profit by them. The question has been asked why did not Palfyn mention his invention in any of his works. This might be answered as follows: The invention of the forceps by Palfyn dates only from 1721, all of his writings appeared before this, excepting the French translation of his surgical anatomy, which was published in Paris in 1726. During these five years Palfyn was working with Devaux on his "Anatomy," and it is probable that their failure to mention les mains de Palfyn, in this new publication, was due to their desire to include nothing in the work which might affect its being recommended by the Royal Academy of Sciences in Paris. It might have been that the case cited by Mauriceau at which Chamberlen used his irons had prejudiced the academicians, most of whom knew of the case, against any similar instrument until its worth had been proved. The forceps had not been generally adopted and Palfyn probably believed that his wide distribution of the instruments themselves among the obstetricians of France, Germany, and Holland was the best advertisment he could give them.

Rist[19] gives the following description of the forceps of Palfyn: "The tire-tête or mains de fer of Palfyn were formed of handles terminating above in two blades of which the concavities adapted themselves to the head of the fœtus. One branch after

the other was applied on the sides of the head and the fœtus pulled thus without hurting it or the mother."

"The blades were of steel, non-fenestrated, 21 cm. long, and 5 cm. at their widest part, gradually tapering as they approached the handles, which were made of wood and almost as long as the blades." (Goffin.[11]) See Fig. 4.

The photographs, Figs. 6 and 7, were taken for the writer some years since, while in Ghent. In Fig. 6 a reproduction of the forceps invented by Palfyn is seen crossed upon his cenotaph.

Laurent Heister,[25] contemporary and friend of Palfyn's, a recognized authority and Professor of Surgery and Obstetrics at Altdorf and Helmstedt, who corresponded with scientists all over the world, writes, eighteen years after Palfyn had presented his forceps to the Academy of Sciences at Paris, as follows:

"The modern physicians and surgeons who were the most skillful in the art of obstetrics have given themselves much trouble to invent an instrument by the aid of which they can save the mother and infant. *Palfyn is the first*, so far as I can learn, who has invented for this end, as I have already stated in article X, a sort of hook with the end large and obtuse, which I have had first engraved in my XXXII Plate, Fig. 16. This author has succeeded in delivering infants whose heads had been fixed and were immobile in the passage without hurting or tearing. But experience has taught me that success with their instruments is difficult and sometimes absolutely impossible, especially when the head is forcibly locked and the instrument has not sufficient grip, so that each of the blades leaves the head when one attempts to pull. I have appreciated for a long time that the instrument of Palfyn needs to be corrected and brought to greater perfection, and with this in view. I suggested in my 'Instructions in Surgery' that the two branches be united by means of a mobile axis or be bound strongly together so that they will press upon and hold the head more firmly and be less liable to slip. I see that my idea has been adopted by many obstetricians who, by joining the two blades on an axis or bond have given the instrument the form of a forceps or pincers by which they can extract either a child alive or dead, with an impacted head. However, when one is convinced of the death of the fœtus I prefer my hooks, Figs. 16 and 17, to the 'English forceps,' as they are accustomed to call them."

After spending considerable on the printing of his works, Palfyn died, at Ghent, on April 21, 1730. He was buried in a cemetery at that time surrounding the Church of Saint Jacques at Ghent. In 1783 and 1784 respectively the College of Medicine at Ghent erected a cenotaph and monument in honor of Palfyn in the Church of Saint Jacques. On the cenotaph, which is of black marble, are represented two branches of oak, the forceps and other instruments invented by him, and below is the following inscription (see Fig. 6):

Et Piis Manibus
Joannis Palfyn
Scriptis Anatomicis Et Chirurgicis
Per Europam Clari Obiit Die 21
Aprilis 1730. Aetatis Suæ 80
Posuit Collegium Medicum
Gandevense MDCCLXXXIII.

The inscription on the monument to Palfyn, evidently suggested by that on the tomb in Leyden, of his friend Boerhaave, reads:

Immortali Palfyni Genio.

## REPORT OF A CASE OF PELLAGRA.

By FREDERICK C. ROBBINS, M.D.,

HORNELL, N. Y.

Mrs. R. P., æt. 42, separated, scrub-woman, born in United States. Grandparents were born in Vermont. Parents were born and spent their lives in Steuben County, New York. There has been found no history of tuberculosis, syphilis, or insanity in the family.

The patient was born in Steuben County, New York, January 25, 1869. She had a meager country school education and has never been out of the county. She married at the age of twenty-five, and has had two children and no miscarriages. The youngest child, a girl of eight years, is normal, but the eldest, a girl of fifteen years, is somewhat backward. After the patient was married she suffered much privation and abuse from a drunken husband, and the last three years had to support herself and children by doing scrub-work and washing. She became slovenly and careless about her personal appearance and her home, and people who have known her well say that her manner had been for some time simple and childish. Her diet has consisted to a great extent of beans, pork, oleomargarine, baking powder biscuit, and during the last winter the family of three used only one ten-pound sack of corn meal.

During the last two years the patient consulted the writer for attacks of jaundice, diarrhea, and for a pronounced lassitude and inability to do any work without much exhaustion. In April, 1912, she worked in an advertising factory for two weeks pasting sandpaper on match-scratchers, having her hands in glue much of the time. In an interview with the factory manager, it was learned that there had been no occupational diseases among the factory hands.

On June 4, 1912, the patient applied for treatment for a small pustule with a surrounding red area on the dorsum of the right hand. Local treatment was of no avail, and the redness extended first over the dorsum of the hand and later the fingers. The redness at first was light in color, gradually changing to a deeper shade, and finally to a dark mahogany color. The dermis was puffy with numerous vesicles showing beneath the epiderm, and at the end of a week the left hand began to be erythematous. The extension was from the dorsum of the hands to the dorsum of the fingers, then on June 11 a slight redness appeared on each wrist, and in three days they were encircled with a triangular point, extending a short distance upon anterior surface of forearms. The palmar surface of hands and fingers was not involved, and at no time was there any dermatitis of any other portion of the body. She next began to complain of prickling and tingling sensations in arms, legs, and the dorsal region became sensitive, and it was noticeable that she always wanted her feet uncovered on account of a constant sensation of heat. In July she did not menstruate, hemoglobin was 60 per cent., blood pressure systolic 128 (Faught); urine examination showed specific gravity 1006, reaction acid, trace of albumin, slight amount of indican, decreased phosphates; blood picture showed a moderate eosinophilia; there was exophthalmos with enlarged thyroid, pulse 96, no tremor. July 21, 1912, a bloody diarrhea of from six to thirty defecations daily set in, which continued till her death. A stomatitis developed, with inability to swallow solids, the tongue being bright red and sensitive. The depression was, at times, marked, but suicidal tendencies were never manifested. She would lie in bed by the hour, seldom speaking, although she recognized everything that went on about her, and would comment on the previous day's happenings. A left Babinski and left ankle clonus developed, which extended to the right with increased knee-jerks. She had complete anuria from June 29 to July 3 with convulsions. She had

A Case of Pellagra.

Cheyne-Stokes respiration; respirations were from three to ten per minute, and pupils did not react. The latter part of July all reflexes were abolished, large decubiti developed, the anus, perineum, and vagina were completely denuded, the dorsum of hands became dry, parchment-like, and had commenced to exfoliate when she died on July 28, 1912.

Autopsy showed a poorly nourished and emaciated adult female, weight about seventy-five pounds, enlarged thyroid; recent hypostatic congestion posterior portion both lungs, slight adhesions lower left lobe of lung; small normal heart with no areas of thickening of the cardiac valves or aorta; increase of connective tissue in liver, gall bladder having thickened walls and containing forty small stones; spleen, increase of connective tissue; stomach dilated and injected; kidneys, cortex thickened, small cysts in cortex of left; intestines injected, several large clots on omentum; uterus and ovaries atrophied; bladder walls thickened; appendix normal.

Microscopical examination of the brain was made by Dr. Charles B. Dunlap of the New York Psychiatric Institute. Gross examination of the brain, which was of good size, was essentially negative; there was slight grayness of the pia, rather unusual tenderness of the brain substance, and a somewhat swollen appearance.

Microscopical examination showed the pia mater everywhere to be rather cellular—sometimes very cellular—the cellular elements being mainly of endothelial type, but a number of lymphocytes and sometimes a few polynuclear leucocytes were also found.

Nowhere in the cortex was there any pronounced neuroglia reaction, at most a few shrunken spiders were present in the first layer. The smaller nerve cells showed dark stainability with often dark, poorly defined nuclei, the so-called "shrinkage alteration" described by Dr. August Hoch. The largest nerve cells (Betz cells) of the motor area and some of the pyramids next in size showed extensive axonal alteration of the type seen in "central neuritis," as described by Dr. Adolf Meyer. These cells also contained a good deal of pigment and fat stains showed considerable lipoid substance in most of the larger nerve cells and about the neuroglia nuclei. The satellite cells were somewhat increased around the nerve cells and along the blood vessels, but not greatly so. The vessels generally were thicker than normal and the small branches entering the cortex were not only thickened but their walls were unusually cellular, a sort of endothelial activity recalling that seen in the pia. No granulations were found in the fourth ventricle.

The cortex in general was orderly and no infiltration was seen in the sheaths of the blood vessels, merely the endothelial and satellite cell increase, as above described.

## DISEASES OF THE LABYRINTH.

### WITH SPECIAL REFERENCE TO THE METHODS OF EXAMINING THE LABYRINTH IN THE CONTINENTAL CLINICS.

By JAMES S. GREENE, M.D.,

NEW YORK.

*Physiology.*—Since the year 1825 various observations have been undertaken to demonstrate a certain connection between the internal ear and movements of the body and eyes. Ewald's experiment proved that there is a connection between the endolymph in any one of the semicircular canals and definite movements of the eyes and head. He made a fistulous opening in the right horizontal canal of a pigeon, 1 mm. behind the ampulla. After sealing the canal behind the artificial opening he used a compression and rarefaction syringe. On compression of the syringe the endolymph could move only toward ampulla, the other end being sealed. On aspiration, the endolymph could move only in the opposite direction, from ampulla to narrow sealed end.

On compression a steady, slow horizontal movement of head and eyes toward the left took place, which (we will shortly see) corresponds to a *horizontal nystagmus* toward the *right*. On aspiration a steady, slow horizontal movement of head and eyes toward the right took place, which corresponds to a *horizontal nystagmus* toward the *left*. This experiment demonstrated that the definite movements of the head and eyes depended upon the direction or course the endolymph took in any given canal.

We have thus seen that Ewald, through his experiment, caused motion of the endolymph with its resulting nystagmus. But what is "nystagmus?"

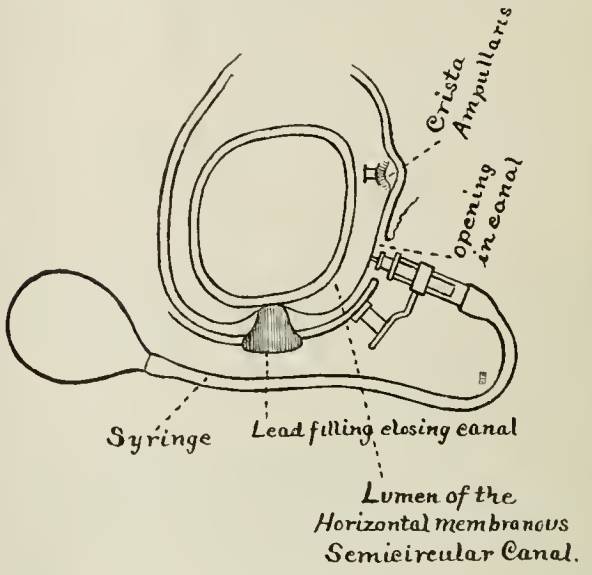

FIG. 1.

What methods (especially for human beings) can be brought into play to produce nystagmus?

*Nystagmus* (from the Greek word meaning to nod) is distinguished by rhythmical movements of the eyes of unequal velocity, and is, therefore, said to have two components, the quick in one direction and the slow in the other. The direction of the nystagmus is designated by the direction of the quick component, as this movement is most easily seen, though in reality the slow component is produced by the vestibular irritation. When the eyes are voluntarily directed toward the quick component it is characteristic of vestibular nystagmus that it increases in intensity and diminishes or ceases completely when the eyes are directed toward the slow component. The hair cells of the ampulla are pulled upon by the flow of the endolymph and this impulse is transmitted through the vestibular nerve to the medulla, and from there to the ganglion of the nerves supplying the muscles of the eye.

Methods for producing Nystagmus: (*a*) Turning Test; (*b*) Thermal: cold water irrigation, hot water irrigation; (*c*) Electrical—galvanic current.

*Vestibular Nystagmus Due to Turning.*—Under physiological conditions we assume that the endolymph in the semicircular canals is put in motion by turning a person and reflexly nystagmus takes place. In order to simplify matters we will assume a person is before us whose left labyrinth has been destroyed (disease). We are testing his right labyrinth. He is placed in a revolving chair with head and body erect. This position brings the horizontal semicircular canal into play so that it can be irritated.

Our subject is being turned to the right, in a direction from the tip of the nose toward the right ear, and we observe that during the turning he has nystagmus (primary) to the *right*. On sudden cessation of turning he has nystagmus (secondary or after nystagmus) to the *left*.

How do we explain this phenomenon? We will now assume that we are observing the right semi-

circular canal from above. When the turning commences the endolymph (and perilymph) move in the same direction in which the canal and hair cells are turning (to the right) (Fig. 2); but through inertia *slower,* so that we get a direct displacement between the endolymph particles and the

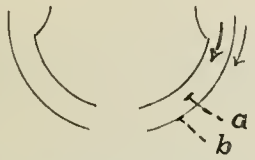

FIG. 2.—Schematic. Right and left horizontal semicircular canal seen from above. Arrow shows direction of movement of (a) endolymph; (b) canal wall.

wall. That is from the canal to the ampulla (Fig. 3).

From the experiment of Ewald we know that such a movement brings forth *nystagmus to the right.* On sudden cessation of turning, the canal remains stationary. The endolymph through its

FIG. 3.

inertia keeps on moving to the right for a short time. We again get a direct displacement between the endolymph and wall; but now in the opposite direction. That is, from the ampulla to the canal (Fig. 4).

We again come back to Ewald's experiment; a movement of the endolymph from the ampulla to the canal, gives us *nystagmus to the left.* In the

FIG. 4.

manner in which we especially irritated the horizontal semicircular canals, we can irritate the other canals. We must simply change the position of the person's head during the turning.

*How to Apply the Turning Test Practically.*—Take your regular revolving office chair. Seat your patient in the chair, the head 30 degrees forward, in order to bring the horizontal canal to a horizontal level in the plane of turning. Nystagmus is diminished through fixation of vision, therefore place a pair of opaque spectacles on the patient or have him shut his eyes or, still better, use on the patient Bartel's convex spectacles, through which you can observe his eyes all through the test; at the same time there is no fixation of vision.

As explained, the patient has nystagmus while turning (primary) and on sudden cessation of turning (secondary or after nystagmus). It is hard to observe nystagmus and turn a patient at the same time. For practical purposes we disregard the primary nystagmus and only observe the after nystagmus, from which we draw our conclusions. It is self-evident that in turning we irritate both labyrinths. It is impossible to irritate one labyrinth when the other is functionating. Ewald's experiment gives us two definite facts:

(1) A movement of endolymph from canal to ampulla in the right horizontal canal denotes nystagmus to the *right*; a movement of endolymph from ampulla to canal denotes nystagmus to the *left.* On the contrary, in the left horizontal semicircular canal, the movement from canal to ampulla causes nystagmus to the *left*, and *vice versa.*

FIG. 5.—Application of the Turning Test.

(2) The endolymph movement from canal to ampulla, in both right and left semicircular canals, causes a stronger irritation of the hair cells than the reverse.

After cessation we know that on turning to the right according to the law of physics, a movement takes place in the right horizontal canal from ampulla to canal and in the left from canal to ampulla (Fig. 6).

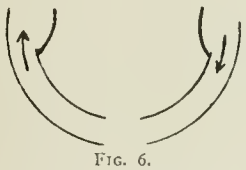

FIG. 6.

The nystagmus produced by this movement will be in the same direction. When both canals have the same irritability the irritation from the left canal will be definitely stronger (movement from canal to ampulla) than the irritation from the right. Thus we can consider the after nystagmus to the left as measuring the irritability of the left semicircular canal. The reverse, the after nystagmus to the right, measures the irritability of the right semicircular canal. When we want to measure through the turning test the irritability of the right semicircular canal, we must turn the patient to the left, in a direction from the tip of the nose toward the left ear. On the contrary, in measuring the irritability of the left semicircular canal we must turn the patient to the right, in a direction from the tip of the nose toward the right ear. In order to induce maximum irritability of the labyrinths, Bàràny found that we must make ten turnings in about twenty seconds.

Florens discovered the law that each semicircular canal produces nystagmus in its own plane. It simply depends on the position of the head. We irritate the different canals according to the relation of the canals to the plane of turning. This is brought about through the various positions in

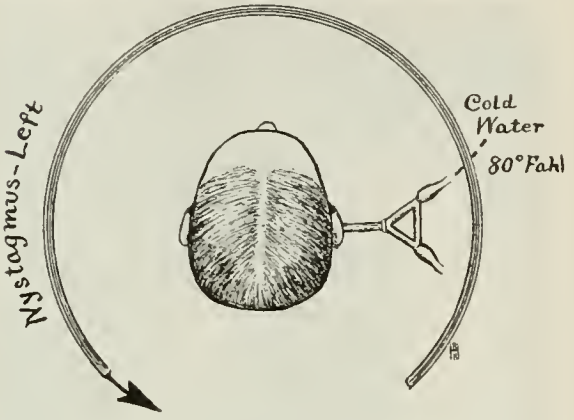

Fig. 7.

which the head is placed. The horizontal canals are best irritated when the head is 30 degrees forward. It is hardly possible to irritate one set of canals alone; usually another set is irritated at the same time, moving the head backward or forward, causing an irritation of the superior canals as well as the horizontal.

We consequently get two kinds of nystagmus, *horizontal* and *rotary*, from the superior canals.

If one is turned with head 90 degrees to the shoulder the superior vertical canal is stimulated. The resulting nystagmus is *vertical* (with relation to the head). If one is turned with head 90 degrees forward, the posterior canal is stimulated. The resulting nystagmus is rotary.

Now, to come back to our patient or subject. Practically it is always necessary to turn in both directions in order to have a ratio of comparison. We have turned him ten times to the right, head 30 degrees forward. On sudden cessation of turning we get horizontal nystagmus to the left, which is pronounced and lasts a certain length of time. That, we assume, is the measure of irritability of his left semicircular canal. We rest a few minutes to allow the reaction of the test to pass and then turn him to the left. We get after nystagmus to the right, pronounced and lasting about the same time. We consequently assume that both canals or labyrinths are equal in regard to irritation. They are normal.

We test a second subject. Turning him to the right, he has after nystagmus, pronounced and lasting. On turning him to the left, he has after nystagmus to the right; it is weak and lasts only about half the length of time. We naturally conclude that there must be some condition present which causes an interference with the normal irritability of his right horizontal semicircular canal (labyrinthine disease). This is the basis of the turning test. After some practice, one tells instinctively the difference in irritability between the two labyrinths.

In general the test is not very reliable, for we are irritating both labyrinths at the same time, and there is no way of telling the amount of influence one labyrinth has on the other.

This brings us to the caloric test, which is superior, because each labyrinth is tested separately.

*Physiological Caloric Nystagmus* (Bárány).—This is made with (*a*) cold water irrigation, or (*b*) hot water irrigation.

We place our subject in a chair, with head and body erect. This is the definite position for irritation of the right horizontal canal. Irrigate his right

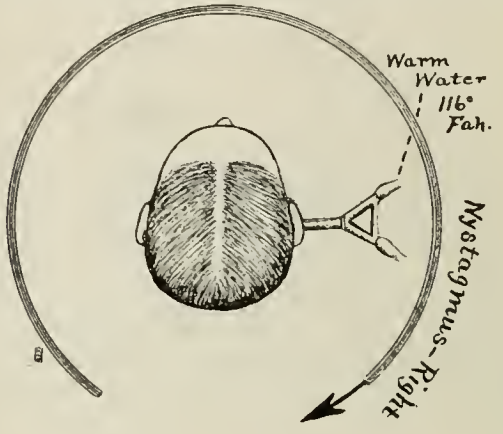

Fig. 8.

ear with cold water. We notice shortly nystagmus to the left (opposite side of irrigation).

What has occurred? The horizontal canal is so placed that when the head is erect so that the zygomatic process is horizontal, the horizontal semicircular canal is not really horizontal. It forms an angle of 30 degrees with the lower surface of the horizontal plane. Now, according to physical law,

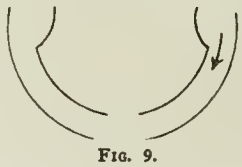

Fig. 9.

when various parts of a definite fluid do not possess a general temperature, usually a movement takes place in the fluid. This movement causes changes in position of the fluid. The heaviest fluid, which is in general the coldest, sinks below. We have the same condition in the labyrinth. When the endo- and perilymph are cooled, a movement takes place toward the lower level; in this instance from ampulla to canal (Fig. 9).

On the other hand, when heated, the movement takes place from a lower to a higher level, *i.e.* from canal to ampulla (Fig. 10). This movement

Fig. 10.

of the endolymph causes a repetition of the Ewald experiment. Accordingly, when we irrigate with cold water and a movement takes place from ampulla to canal we get nystagmus to the side opposite the irrigation.

On the contrary, irrigating with warm water causes a movement from canal to ampulla, and the resulting nystagmus is to the right or side of irrigation.

We must credit Brünings for his ingenuity in putting the application of this test on a standard practical basis. Working on the theory that the canal is a ring in which fluid (endolymph) is moving, he showed through a series of experiments

that the most favorable condition for the movement of endolymph to take place in the horizontal canal was when the canal was in a vertical position. This was designated by him as the "optimum stellung" (optimum position) (head 60 degrees backward). The contrary, where the canal was

Fig. 11.—The Optimum Position

horizontal, head 30 degrees forward, he designated as the "pessimum stellung" (pessimum position), it being unfavorable for endolymph movement. Caloric nystagmus, due to irritation of the horizontal semicircular canal, attains its maximum in the optimum position, and is almost or completely extinct in the pessimum position.

To come back to our patient. He is seated, head

Fig. 12.—The Pessimum Position.

60 degrees backward and right ear is being irrigated (with cold water). Doing the test roughly, we bend the subject's head backward and guess when it is about 60 degrees. We take a Politzer bag or a douche bag, with rubber tubing attached and pointed or olive tip at end of the tubing, and irrigate the ear until nystagmus takes place. Bárány advised 80° F. when using cold water and 116° F. when using warm water. All this was a matter of guesswork. The strongest factor in judging the irritability or non-irritability of a labyrinth was personal and practical experience through con-

Fig. 13.—The Otogoniometer.

tinued observation. There was no standard to go by. All this is done away with through the two splendid instruments invented by Brünings: The *otogoniometer* and *otocalorimeter*.

*The Otogoniometer.*—The principle of the otogonimeter is to show the direction of the horizontal semicircular canal and to place the eyes in a lateral position without causing interference with convergence and accommodation. It consists of a self-retaining metal band, which fits around the head. There is also a fixed semicircular scale (*a*) and a movable scale (*b*), to which is attached a pointer (*c*). The instrument is fastened on the patient's head so that when the pointer is horizontal it is in a direct line with the zygomatic process. The pointer is then moved 30 degrees upward according to the attached scale, so that the pointer and an imaginary line through the central axis of the horizontal canal unite. The head is then bent backward until the pointer is vertical. The horizontal canal is then in a vertical position, or after Brünings in the optimum position. There is a second movable pointer (*d*) which glides in a right and left direction on the fixed semicircular scale. It has a small mirror attached to the extreme end. The mirror is set so that the person tested sees the reflection of some object in the room. When the rod is placed on the scale marked 50 degrees the line of vision is correct. Fixation of vision takes place without accommodation and convergence. When fixation occurs with accommodation and convergence it has a disturbing influence on nystagmus.

*The Otocalorimeter.*—The otocalorimeter is an instrument that allows us in a practical way to measure the irritability of the labyrinth through the definite quantity of water used when irrigating. It consists of two glass receptacles, a large one above with thermometer attachment, for holding a quantity of water of a definite temperature; and a small one below, which serves to measure the quantity of water used until the instant nystagmus sets in.

One of the important features of the otocalorimeter is the ear piece, because it gives us regularity in introduction and excludes trauma. It consists of a double current metal olive, which is connected to both glasses with two rubber tubes. Water leaves the upper glass, goes to the ear, then flows into the measure glass below. There are 3 scales

on the measure glass. The first designates the quantity of water used, the second and third designate directly the irritability of the labyrinth under examination, measured through the quantity of water used until we get nystagmus. This irritability is compared to a normal standard which corresponds with an assumed normal labyrinth that gives nystagmus after using 70 c.c. of water, temperature 27° C. (80.6° F.). So that figures below the assumed normal standard (1 in diagram) signify exaggerated irritability; above, diminished irritability.

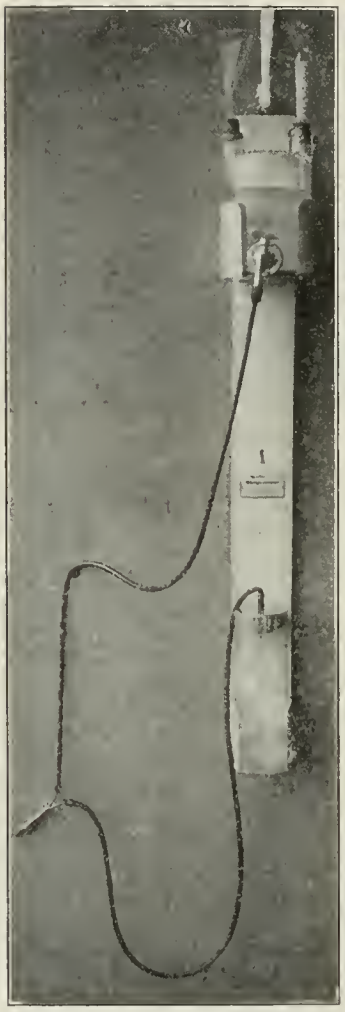

Fig. 14.—The Otocalorimeter.

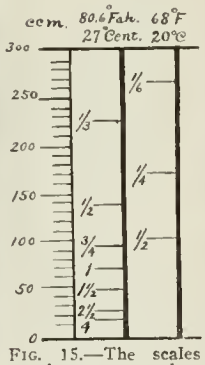

Fig. 15.—The scales on the measure glass of the otocalorimeter (enlarged).

When the irritability of the labyrinth is not greatly changed Brünings recommends the use of water 27° C. (80.6° F.) as cold irrigation. When irritability is extremely diminished he employs water of 20° C. (68° F.). In using warm water he recommends a temperature of 47° C. (116.5° F.). The object is to create a similar difference in number of degrees between the body temperature and the temperature of the irrigating fluid. The body temperature being 37° C. (98.5° F.), cold water used should be 27° C. (80.6° F.) and warm water 47° C. (116.5° F.); a difference of 10° C. (18° F.) above and below body temperature. To *recapitulate*: Take our patient, attach the otogoniometer, move the scale 30 degrees above the fixed scale, then move the head backward so that the pointer is vertical. Set the pointer with mirror attached laterally; to the opposite side when irrigating with cold water and to the same side when using warm water. See that the patient observes a distant object in the mirror. Irrigate with the selected cold or warm water until nystagmus sets in. The amount of water used gives us the measure of irritability of the tested horizontal semicircular canal.

*Galvanic Nystagmus.*—We place an electrode (current 10-24 m a) before the tragus of the right ear of a person. The other electrode he holds or it is placed elsewhere on the body. We find that if the electrode in front of the ear is the anode (+) he will get nystagmus to the left. If we replace the anode (+) by the cathode (—) we get nystagmus to the right.

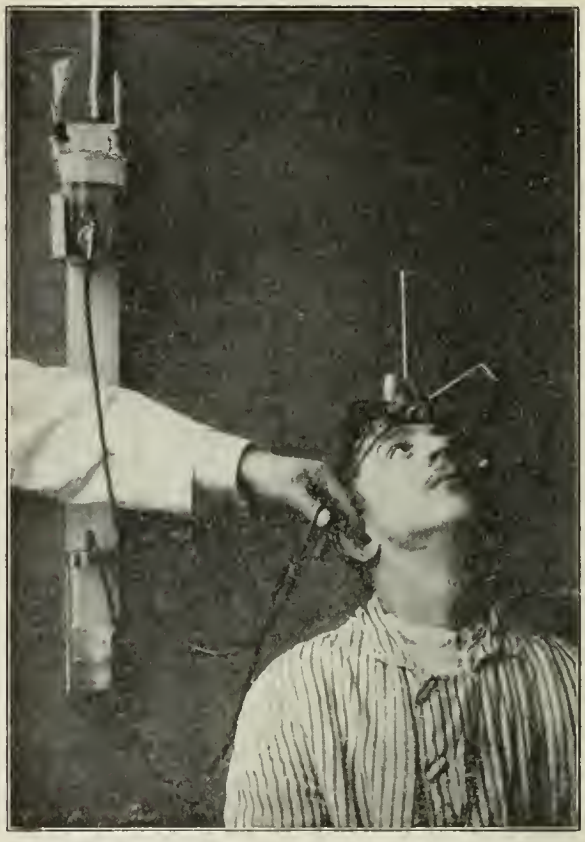

Fig. 16.—Practical Application of the Caloric Test.

Some authorities assume that the galvanic electric current directly stimulates simultaneously the terminal filaments of the vestibular nerve and the nerve itself. According to other authorities (Brünings) the galvanic electric current produces a similar movement of the endolymph (cataphoresis) to that the turning or irrigation induces.

Besides nystagmus, in which the eye muscles are involved, there are other muscles that are affected through irritation of the labyrinth with its resulting nystagmus. For example:

*The Bárány Indication Test.*—When a person has nystagmus and is told to point at a certain object, he will point either to right or left side of object, depending on his nystagmus. If he has nystagmus to the right, he will point to the left of the object, and vice versa. In a differential diagnosis between certain cerebellar and vestibular conditions, the indication test is an important factor. Another one of the principal symptoms resulting from irritation of the labyrinth is vertigo.

*Vertigo,* used synonymously with dizziness, is a sensation of movement a person experiences, whether he is really moving or not; this may be accompanied by reeling, and surrounding objects ap-

pear to be moving in some definite direction when in reality they are at rest. Vertigo in general may occur with or without any recognizable nystagmus. Labyrinthine vertigo is almost always accompanied by nystagmus.

We thus possess a means by which we can artificially produce vertigo. When this vertigo reaches a certain degree of intensity it is associated with objective symptoms. The patient is uncertain in gait and posture; he may even fall. When he falls through vertigo due to the labyrinth, the direction in which he falls always depends on the direction of the nystagmus. Thus, horizontal nystagmus to the right causes falling to the left and vice versa. Horizontal nystagmus to the left with the head turned 90° to the shoulder, causes falling to the front. Horizontal nystagmus to the left and head turned to right shoulder 90° causes falling backward.

The above facts are of vast importance when we attempt to make a differential diagnosis between labyrinthine disease and cerebellar disease. In cerebellar disease the direction that one falls is not regularly influenced by the direction of the nystagmus.

The objective symptom of vertigo, the tendency to fall, can be made more evident through the Romberg phenomenon.

*The Romberg experiment* consists in having a person stand with eyes closed and feet together. When there is no disturbance in static function the person will keep his equilibrium. When there is a disturbance he will have a tendency or fall to one side. The position in which we keep our body is due to three factors—tactile sense, optic sense, and vestibular static function.

In order to sustain equilibrium at least *two* of these three factors are necessary. Through simple closure of the eyes, one factor is eliminated. When the tactile (tabes dorsalis) or vestibular sense (labyrinthine disease) is destroyed, equilibrium is not sustained and Romberg is positive.

*Turning Sensation.*—The subjective turning sensation that the patient experiences is in relation to the direction of the nystagmus. Nystagmus from left to right gives the illusion that surroundings turn from left to right, and vice versa.

*Vascular and Gastric Disturbances.*—Occasionally we get pallor, nausea, vomiting, sea-sickness, etc., with nystagmus. These accessory symptoms are in general not very pronounced in cases of experimental nystagmus of a normal person. They may reach a high degree of intensity in some nervous conditions, especially neurasthenia and traumatic neuroses.

*The Comparative Value of the Different Labyrinthine Tests.*—The turning test is far easier to put in execution than the other tests, but it has two disadvantages. It is impossible to test each labyrinth separately and in cases of severe sickness it is really not permissible.

The galvanic test has the same disadvantages. Definitely each labyrinth can not be tested separately and occasionally, especially in nervous individuals, very disagreeable secondary effects follow.

The caloric test has one immense advantage that surpasses all its disadvantages. We are able to test each labyrinth separately. It is understood, that in measuring the excitability, as for example with Brünnings' system, we must take into account local conditions, which influence the conduction of the temperature, viz., stenosis of the external auditory meatus, polyps, inflammation of the middle ear, the condition of the drum membrane, presence of secretion, of cholesteatoma, etc. Again it is not always possible to carry out the test as advised with water, as in cases of dry perforation. In such cases, water is supplanted by paraffin or air (hot or cold) (apparatus from Lautenschläger). Notwithstanding these disadvantages, the caloric test at present is the major test.

*Pathology.*—There are a great many diseases of the labyrinth and its nervous system: (1) Intoxication (neuritis nervi vestibularis). (2) New tissue formation (tumors, etc.). (3) Conditions arising through vascular troubles (Ménière's disease). (4) Inflammations.

Of all these conditions the ones which interest us most are the inflammataions. How do they occur?

A primary spontaneous labyrinthitis, until the present, has not been positively observed. Those cases which were assumed to be such in all probability were and are the results of cured meningitis. We have to assume, with the exception of direct infection of the labyrinth, that all inflammatory conditions of the labyrinth are secondary inflammations, the sequels to other morbid processes in the system. The conveyance of the morbid agent can be effected (1) directly, (2) through vascular channels, (3) through extension by continuity. Besides a labyrinthitis the consequence of an accidental traumatic condition (fracture of the base) the *first group* is the most important of the forms of operative labyrinthitis. These may occur through direct infection; or the operative procedure may cause a latent inflammatory condition existing in the labyrinth to become acute; or finally an operation may cause an extension of a middle ear process to the labyrinth.

Under the *second group* (vascular channels) we note that morbid agents can be transported by way of arteries from distant parts of the system to the labyrinth and produce a metastatic labyrinthitis as in typhoid fever. Cases of labyrinthitis occurring through the venous system (phlebitis) are very rare.

The *third group* is that in which extension occurs by continuity. The labyrinth itself forms a system of cavities. The cavity of the middle ear lies on one side, and the encephalic cavity on the other. According to the source of infection, Goerke designates the condition as either a tympanic or an encephalic labyrinthitis. There are several natural ways through which an infection can pass from the encephalic cavity to the labyrinth. Among these may be mentioned the lymphatic spaces of the sheath of the auditory nerve, the ductus vestibularis (endolymphaticus), and especially the aquæductus cochleæ. Between the labyrinth and the series of spaces (tympanic cavity, eustachian tube, mastoid cells) there does not exist, with the exception of the vascular system (which can hardly be taken into consideration) any natural communication.

A propagation of infection from the series of spaces into the labyrinth can occur only after rupture of the labyrinth capsule. These penetrations into the labyrinth occur usually in the following order: the fenestræ, promontorium, and horizontal emicircular canal.

*Labyrinth Inflammations.*—The inflammatory conditions of the labyrinth (labyrinthitis) may be classified according to extension or according to the nature of the inflammatory condition. According

to the degree of extension there exists a circumscribed labyrinthitis, in which the inflammation is localized in one part of the labyrinth; or there may be a general labyrinthitis in which the entire labyrinth is involved. According to the kind of inflammation, we have on the one hand a serous labyrinthitis, and on the other a plastic labyrinthitis, which is only a form of healing process of these exudative inflammations.

*Outcome of the Several Forms of Labyrinthitis.*—The *circumscribed* form may continue to exist as such. It may also abate or through some condition become a general labyrinthitis. We must not forget to consider that there is a great tendency for inflammations of the labyrinth to become encapsulated.

The *serous labyrinthitis* may subside completely with conservation of function, or, on the other hand, pass into a plastic or purulent form.

The *purulent form* can also abate, but only after partial or complete loss of function, and change into the plastic form. When it does not abate, it progresses and causes cerebral complications. The channel of propagation can occur through the natural existing communications (ductus endolymphaticus, ductus perilymphaticus, meatus internus, vascular system) or through artificial ways created by the morbid process.

*Acute Exclusion of the Function of One Labyrinth.*—There is a train of general symptoms that goes with all cases of acute exclusion of the labyrinth regardless of cause and form. The condition may be due to acute purulent labyrinthitis, hemorrhage in the labyrinth the result of arteriosclerosis, leukemia, syphilis, fracture of the base of the skull, etc. Following the injury we get spontaneous symptoms, subjective and objective, such as nausea, vomiting, vertigo (with disturbance in equilibrium), and nystagmus, rotary and horizontal to the sound side. The patient assumes a characteristic position in bed. He lies on his sound side; which is always the side to which he has his spontaneous nystagmus (quick component). We know that vestibular nystagmus is diminished by looking in the direction of the slow component and increased by looking in that of the quick component. From the position assumed in bed the eyes are directed toward the slow component and all annoying symptoms are relieved. The patient finds lying more comfortable, for as soon as he tries to sit up, nausea, vomiting, severe vertigo, with apparent movement of surrounding objects, set in. A sensation of turning the body and inability to walk are often complained of.

A patient with the above spontaneous symptoms reacts in a certain measure when put through the different tests and we get a train of induced symptoms. The turning test in a case, where the right labyrinth is excluded, will give stronger after nystagmus to the sound (left side) on turning to the right than to the diseased side when turned to the left. The nystagmus to the diseased side usually lasts about 15 to 20 seconds. The nystagmus to the sound side about 15 to 40 sec.

The caloric reaction shows that the diseased labyrinth responds slightly or not at all to the irritation of the test. We derive the same results from the galvanic test. In case the condition in the labyrinth is such that there is an erosion of the bony wall (a fistula), we can (when the labyrinth is still capable of functioning) often induce a new phenomenon, viz.:

*The Fistula Symptom.*—Through compression and rarefaction of the air in the external auditory canal and tympanic cavity we get nystagmus. Compression and aspiration of the membranous canal through the fistula in the bone causes active nystagmus of some seconds' duration. The direction of the movement differs in different cases. Compression is always opposite to that of aspiration.

*Practical Application of the Fistula Test.*—An olive-shaped tip fitted into a Politzer bag is inserted tightly in the external auditory meatus of the diseased (say the right) ear. While the patient looks directly forward, sudden strong pressure is made on the bulb. When a fistula is present and the labyrinth is still functionating nystagmus will occur in most cases to the right and seldom to the left side, and by aspiration in most cases to the left and seldom to the right side.

As stated, the above enumerated symptoms come on suddenly. They can last a certain length of time and gradually abate. In rare cases, in addition to the labyrinth affection we get cerebral complications.

The opposite to this very acute form of labyrinth exclusion is a

*Latent Exclusion or Destruction of the Labyrinth.*—We will assume that one side is affected. The patient complains of attacks of vertigo, which may some on suddenly, and last from a few seconds to a few minutes. These attacks may be associated with or without an external cause. The external causes are rising or inclining the head backward or to the diseased side, rapid movements of the head, stooping forward, going from a hot to a cold room, or vice versa. The patient may quietly sit or sleep. An attack may occur while walking. There may be some nausea, but vomiting, as a rule, is not present. In general, when the eyes are in the extreme lateral position (either right or left), there occurs a weak, spontaneous rotatory or horizontal rotatory nystagmus, which is not influenced by movements of the head.

Caloric test of the diseased side is negative, no reaction. Caloric test of the sound side gives distinct rotatory nystagmus. Galvanic test of the diseased side for both anode and cathode is negative, or nearly so. Aspiration and compression tests are negative. The turning test, to the diseased side, head erect, produces horizontal after nystagmus to the sound side of about 30 seconds' duration. Turning to the sound side produces horizontal after nystagmus of about 15 seconds' duration. Usually the nystagmus due to the diseased side lasts about half the length of time of the sound side. There are no disturbances in equilibrium. The patient always gives some history of a running ear, acute or chronic, and of impairment of hearing. (The cochlea is usually involved.)

To come back to our classification, we will now assume we have a patient with a

*Circumscribed Labyrinthitis.*—The patient complains of attacks of vertigo as his main trouble. On going into his history you find he has an acute or chronic middle ear suppuration of some standing. There is impairment of hearing or complete deafness on affected side and occasionally tinnitus. His vertigo occurs with or without an external cause; practically the same as that described under latent labyrinthitis. The attacks may last from several seconds to several hours. They are accompanied by nausea, disturbances in equilibrium and sometimes vomiting. In the interval between attacks the patient feels per-

fectly well. On examination during an attack you find nystagmus, usually to the sound side. Occasionally the nystagmus is also seen to the diseased side. The caloric test and the turning test give an almost normal reaction. In these cases the fistula phenomenon is of prime importance. It is a great diagnostic point in differentiation between a diffuse labyrinthitis and a circumscribed. So long as the fistula symptom is present we can exclude a diffuse labyrinthitis.

A circumscribed labyrinthitis usually commences as an acute or chronic suppurative otitis media, then an erosion of the labyrinthine wall (fistula) occurs, with the resulting circumscribed labyrinthitis.

*Diffuse Labyrinthitis* (Serous, Purulent).—In our anatomical classification we mentioned a serous and purulent labyrinthitis. The difference is not only of an anatomical pathological significance, but is of great clinical value, especially from a prognostic and therapeutic standpoint.

The serous form almost always abates, while the purulent form has a worse prognosis. Operative interference is not necessary in the serous form, while in the purulent form it usually is. In both forms we get the general symptoms that have been described under acute destruction of the labyrinth. The symptoms are much stronger in the purulent form than in the serous form.

The presence of fever and complete loss of function of the labyrinth (total deafness, etc.) are almost positive signs that we are dealing with a purulent labyrinthitis. In the serous form we can also have almost complete loss of the labyrinth function, but in general the function is present to a certain extent.

*Diagnosis.*—Making a résumé of all that has been said of labyrinth disturbances, we notice two symptoms stand out prominently—vertigo and nystagmus. There are a great number of conditions that give vertigo and nystagmus besides labyrinthine affections. In making our diagnosis these conditions must always be thought of and taken into consideration. The history of each case is significant and of prime importance. A thorough examination of the ear and the application of the various tests almost always show if there is any connection between the spontaneous attacks of vertigo or vertigo and nystagmus, of which the patient complains, and the labyrinth.

Practically nystagmus always exists when the vertigo is of labyrinthine origin. The presence or absence of fever must be carefully looked into. Patients suffering from neurasthenia, arteriosclerosis, menopause have spontaneous attacks of vertigo with or without nystagmus. Those suffering from toxic influences, gastrointestinal trouble, smokers and drinkers have spontaneous attacks; almost all persons who have received an injury about the *head* complain of vertigo. These cases are of medico-legal interest. The history of the cases, the local ear condition, and the response to the various tests lead us to the correct diagnosis.

In meningitis we very often get nystagmus which is of intracranial origin, not vestibular. We base our diagnosis on the general meningeal symptoms present. Temperature, severe headache, vomiting, severe stiff neck, hyperesthesia, lumbar puncture, cloudy fluid, abducens-paralysis, the Babinski, Koenig, choked disc signs, etc.

The differential diagnosis between some cerebellar affections (tumor or abscess) and labyrinthine conditions is difficult. In both we usually get vertigo and nystagmus. The following table may aid in differentiation:

| Cerebellar Disease. | Labyrinthine Disease. |
|---|---|
| Nystagmus: Directed to diseased or sound side or both; to diseased side somewhat stronger. General tendency to grow stronger or may remain the same. Usually rotatory. | Nystagmus: Directed to sound side. Tendency to diminish and cease; Usually horizontal; may be both. |
| Labyrinth usually responds to tests. | Response to tests diminished or lost. |
| Choked disc usually present. | Choked disc absent. |
| Patient usually lies on diseased side. | Patient lies on sound side. |
| Placing patient on sound side increases his vertigo, vomiting and pulse. | Placing patient on diseased side increases his vertigo, vomiting and pulse. |
| Romberg Phenomenon: Eyes shut and feet together, patient sways or falls to either side, not depending on nystagmus or position of head. | Romberg Phenomenon: Eyes shut and feet together, falls or sways to diseased side, or depends on direction of nystagmus or position of head. |

It is of practical value to make this last comparison somewhat clearer. We have said that there exists in a majority of cases a definite connection between the direction in which a patient has a tendency to fall and the direction of his nystagmus when due to labyrinth disease, namely, nystagmus to the right, tendency to fall to the left and vice versa. In cerebellar affections (especially conditions of the vermis) the above definite connection does not exist. When we produce nystagmus to the right, instead of falling to the left, as in vestibular disease, patient may fall to the right or some other indefinite direction. There is absolutely no connection between the direction of falling and the nystagmus.

Lately Bárány brought out the "indication test," a test that is of vast importance in a differential diagnosis between labyrinth and cerebellar disease. Normally, when a person is shown an object, then told to shut his eyes and point with index finger at that object, he will do so correctly (Graefe's test.) When we induce nystagmus and no pathological condition is present a person will point to the right or left of the object, depending on his nystagmus. When a person has cerebellar disease, with or without having nystagmus, he will point spontaneously, not depending on nystagmus, to the side of the object. Where we induce nystagmus in such a person through any of our tests, we find that his pointing is hardly or not at all influenced. He continues pointing, as he did previously, spontaneously, almost or completely to side of object.

*Treatment.*—An acute labyrinthitis following an acute otitis media should not be operated. Rest and local treatment of ear may suffice. If operated, free exposure of the antrum mastoideum in the usual way is sufficient. *A circumscribed labyrinthitis* following an acute or chronic suppurative otitis media should be treated conservatively (rest, etc.). The local ear condition should be treated in the usual manner. If after sufficient observation operative interference is found necessary, do a radical mastoid operation and examine carefully the horizontal semi-

circular canal and promontory for fistula, caries and granulations. If the labyrinthine symptoms abate, the conservative treatment of the labyrinth was correct. If they continue or become aggravated, a labyrinth operation, partial or complete, is indicated.

A middle ear condition may cause a *diffused labyrinthitis* primarily, or a circumscribed labyrinthitis can become diffused, especially following a radical mastoid operation. If the condition is a diffused serous labyrinthitis, it is not grave and operative interference is not necessary.

If the condition is a *diffused purulent labyrinthitis,* it is dangerous. Very often complications set in—meningitis or brain abscess. As soon as a diagnosis is made, operate, if possible, before complications set in. There are several standard methods of doing a partial or complete labyrinth operation; the object in view is the removal of all diseased tissue and establishing free drainage.

1. The carious portion of the horizontal semicircular canal may be removed with a sharp curette.

2. The canal and promontory may be opened, curetted, and drained, either laterally or medially. By laterally, we mean opening the horizontal canal and proceeding upwards to the vestibulum, which is also opened. Medially, we open the vestibulum by way of the fenestræ and proceed to the horizontal canal.

3. The canal, promontory and spindel of cochlea (if found carious) should be removed.

4. The posterior portion of pyramid up to the internal auditory meatus is removed. This destroys the posterior and horizontal semicircular canals. Then the promontory is removed.

In doing the labyrinth operation there is always danger of injury to the facial nerve and a paralysis may occur. Bourguet's facial protector is recommended by some authorities.

## SUBCUTANEOUS RUPTURE OF THE KIDNEY.*

By F. C BEALL, B.S., M.D.,

Fort Worth, Tex.

Associate Professor of Surgery, Medical Department, Texas Christian University.

Injuries of the kidney are by no means of common occurrence, and the experience of any one man with them is necessarily limited. As to their frequency, Küster, in 7,740 injuries at his clinics at Basel and Berlin, saw only 10 cases; of these only 1 was an open wound. In 2,610 autopsies following injuries there were 13 in which the kidneys were damaged. Only one of these was of a penetrating nature. Israel records, notwithstanding a large experience of renal surgery, only one operative case (Ransohoff in Keen's Surgery). Statistics of wounds of the kidney have been collected by Maas, Keen, Küster, and others. The analysis of Keen's 155 cases shows 19 gun-shot wounds, 8 penetrating wounds, 118 subcutaneous ruptures, 2 partial nephrectomies from rupture, 6 traumatic hydronephroses, and 2 ruptured ureters. From this it will be seen that the subcutaneous rupture is by far the most common form of kidney injury.

Subcutaneous rupture of the kidney is much more common in men than in women. Of 299 cases collected by Küster 281 occurred in men. Küster says that injuries of the loin in men are more apt to cause rupture of the kidney than in women, in whom mobility of the kidney more easily occurs. The great preponderance of men over women in this series of cases is easily explained, however, by the greater exposure of men to injuries of all kinds. Rupture of the kidney is, as a rule, the result of direct violence. The mechanism of the production of the injury has been made the subject of experimentation by Küster, who has tried to show that in most cases it is due to the effect of a force (hydraulic in nature) acting through full vessels and a full pelvis, causing the kidney to burst along the lines radiating from the hilum in the direction of the tubules—that the kidney driven against the spine by the impact of the lower ribs, if distended by fluid, will tend to tear at the point of maximum impact of the ribs in a direction transverse to its long axis. It has been suggested that the direction of the rupture radiating from the hilum to the periphery is influenced by the lines of least resistance, indicating the original absence of vascular loops and of their accompanying connective tissue between the adjoining lobules of which the fetal kidney is composed (Piersol's Anatomy). In cases of crushing injuries of the side, laceration by direct impact of a rib may occur. This, however, is uncommon, as the ribs which are in immediate relationship with the kidney, the eleventh and twelfth, are but rarely fractured. Still more uncommon is rupture from muscular action alone. The mechanism in such cases is the same as in the cases due to direct violence, the violent muscular action adducts the ribs, forcing them against the kidney, and the kidney against the spine. Forcible anterior flexion of the spine, as from a weight falling on the shoulders, may cause compression of the kidney between the lower ribs and the ilium, and is, therefore, not infrequently followed by hematuria, indicating some degree of rupture of kidney substance (Piersol).

*Paper read before the Northwest Texas Medical Society, January, 1912.

Injuries of the kidney and its coverings may vary in degree from simple contusion to extensive ruptures or complete pulpifying of the kidney substance. The contusion may involve only the cortical portion of the kidney, or rents may extend deep into the kidney and involve the pelvis and larger renal vessels. According to the extent and location ruptures may be divided as follows: (1) Incomplete, *i..e.* involving the parenchyma alone, the symptoms being those of excessive renal tension; (2) complete internally, into the pelvis of the kidney; (3) complete externally, extending through the fibrous capsule; or (4) complete, involving both the pelvis and the capsule. Another, or transperitoneal group may be added, in which the peritoneum is involved in the external tear. Such cases are relatively much more common in children because of the absence of the perirenal fat. Tears on the surface of the kidney usually run horizontally or radially from the hilum with the tubules, and are most often on the anterior which is the least supported surface of the kidney. These injuries are often complicated by other lesions, as fracture of the ribs, fracture of the spine, and rupture of other abdominal viscera.

The symptoms of rupture of the kidney are general and local; primary and secondary. The primary general symptoms are those of any other severe injury, the symptoms of shock and hemorrhage. However, extensive injury to the kidney may occur without signs of shock appearing for some time. The primary local symptoms are pain, tenderness, and swelling in the region of the kidney and hematuria. The pain is dull and deep-seated, though paroxysmal attacks of acute pain may be caused by the passage of blood clots along the ureter. As perirenal extravasation ensues, the pain becomes more diffuse. Changes in position and deep inspiration increase it.

The swelling varies with the degree of the injury. It is caused by extravasation of blood and urine into the perirenal tissues. It is diffuse and ill-defined. If the peritoneum has been torn, symptoms of acute peritoneal irritation are manifest, though we may have tympanites, muscle spasm, and tenderness on the affected side from the retroperitoneal irritation which, in the presence of a large effusion especially, may be misleading. In a case of my own the only question at all about the diagnosis was whether or not there was intraperitoneal trouble. Occasionally a blocking of the ureter by a blood clot will give rise to a hydrohematonephrosis, in which case the feeling is distinctly of a localized and movable mass—the distended kidney.

Hematuria is the most valuable of the local signs, as pointing to the exact nature of the trouble. Pain, tenderness, and swelling in the loin may come from other sources than the kidney, but when we have those combined with the presence of blood in the urine the diagnosis can hardly remain in doubt. Hematuria is present in a very large percentage of the cases. It occurred in sixty-five of seventy-one cases tabulated by Maas, and eighteen out of twenty-six cases reported by Morris. It comes on soon after the injury and varies in intensity and duration. The urine may be simply smoky or contain such a quantity of blood as to clot readily. The hematuria may last for a few hours or many days, and may be followed by an albuminuria, which persists for a greater or lesser length of time. In some cases injury to the cortex of the kidney occurs without the presence of blood in the urine.

The secondary general and local symptoms are due to changes that take place in the kidney and perirenal tissues from infection or reactional processes following the injury and exudation of blood and urine. Infection may take place, ascending from the bladder in cases of catheter cystitis or other bladder inflammation, or by the migration of microorganisms through a weakened intestinal wall, or through the blood stream. In such cases the symptoms are those of an acute peritonitis, or an acute perinephritis. Aneurysm of the renal artery has been reported as the result of injury to the kidney, and hydronephrosis may be the result of previous trauma. The injury of the kidney itself may lead to infection with localized abscess formation, or a unilateral chronic nephritis. Anuria has been noted even where the injury was unilateral and of slight degree.

The chief immediate danger from rupture of the kidney is the hemorrhage. The late danger is infection. The outlook in any case depends on the degree of the injury. In 108 cases collected by Grawitz, 58 recovered. Many of the fatal cases had associated injuries of other organs. In fourteen instances the primary hemorrhage caused death, in seven suppurations of the kidney, and in three anuria. Of Küster's 306 cases, 222 were uncomplicated and had a mortality of 31 per cent. The injury is much more grave in children. The figures of Maas show a mortality of 85 per cent. in children under 10 years.

In many cases of rupture of the kidney spontaneous recovery takes place. With only a slight hematuria, a moderate amount of swelling in the lumbar regions, and the absence of the signs of shock, rest in bed may be all that is necessary to effect a cure. Strapping of the parts and anodynes may be necessary to relieve pain. Ergot, adrenalin, and other internal or hypodermic medication is of doubtful value in controlling the hemorrhage. The rest in bed should be prolonged as the hemorrhage is likely to recur. When the hematuria is severe, when a lumbar hematoma is growing, or when there are signs of intraperitoneal trouble, immediate operation is indicated. In cases of continued or intermittent hematuria it is better to risk a possibly unnecessary exploration early than to let the patient get into a condition unsatisfactory for operation.

The nature of the operation must depend upon the conditions found when the kidney is exposed. Where possible rents should be sutured or packed, and more or less completely severed portions of the kidney should be removed. The indications are to control the hemorrhage in some way and to provide a means of egress for the extravasated fluids. Extensive laceration or rupture of the larger renal vessels will necessitate nephrectomy.

Statistics show that, except in cases of mild contusion, early exploration gives the best results. Delbet collected 319 cases, of which 225 were treated without operation, with 103 deaths. In 50 cases the kidney was treated by suture, packing, or partial resection, with two deaths. In 44 cases primary or secondary nephrectomy was done with 11 deaths. The largest table collected is that of Watson. Of 273 cases treated expectantly, 81 died, a mortality of 30 per cent.; of 99 treated by a conservative operation, 7 died, or 7 per cent.; of 115 treated by nephrectomy 25 died, or 22 per cent. When it is considered that the majority of cases treated expectantly are those of mild degree and that those operated upon are the severer ones, and

that in many instances the operation is long delayed, there can be no doubt that early operation for rupture of the kidney is a life-saving measure.

I wish to append a brief history of a case that came under my observation a few months ago.

S. W., male, age 9. On May 28, 1911, a heavy empty barrel fell from a third-story window and (we could never learn just how, but probably on the rebound from the ground) struck the patient on the left side over the lower ribs. A physician was called who administered "first aid," and had him removed to his home. That night his family physician was called and he, as soon as he could obtain a specimen of urine, found that it contained blood. The boy's pulse from a short while after the injury was accelerated, his temperature somewhat elevated, and he complained of intense pain in his left side. His condition showed no improvement, and two days after the injury he was removed to a hospital where I saw him. Despite the early administration of a cathartic, his bowels had not moved in the forty-eight hours following the injury.

Examination showed a well-nourished boy lying propped on his left side with thighs and legs partially flexed and an expression that depicted great suffering. His temperature was 101°, pulse 120, and respiration 34. He could be made to turn on his back, but handled himself with great care and complained bitterly of pain while lying in that position; and would immediately turn back onto his left side when we would let him. His chest was resonant throughout on percussion, and the breath sounds everywhere were clear. The breathing was shallow and the patient complained of pain in his left side on taking a deep breath. The lower left side of his thorax and loin were covered with strips of adhesive plaster. The abdomen was distended, motionless, and everywhere tympanitic, except in the left loin, where there was an ill-defined area of dullness extending to about the anterior axillary line. The muscles of the left side of the abdomen were more resistant than those on the right, and palpation over the upper left side and loin was painful. A specimen of urine obtained at about this time was clear to the naked eye, and in view of this fact and that his general condition seemed a little improved, we decided we could safely watch him for a few hours more. The next morning, however, the urine again contained a large amount of blood and the dullness in the left side had grown definitely larger and we decided to make an immediate exploration of the kidney. The question came up on account of the tympanites, muscle-spasm, and constipation as to whether there might not be blood in the peritoneal cavity. We did not think so, however, because there had been no crampy pains and no nausea.

With the patient in a face-down position the kidney was exposed through a vertical incision. On opening the internal sheath of the quadratus lumborum muscle a dark, bloody fluid with urinous odor began to well up into the wound. On sponging this away we could see that the kidney was lacerated near its lower pole, and that considerable active bleeding was still going on. The lower one-fifth or one-fourth of the kidney was separated from the remainder by a tear that extended into the pelvis on the anterior surface. Where this tear reached the convex outer border there was another vertical tear extending up and down about an inch each way, and the radial tear extended around onto the posterior surface of the kidney for about an inch. The kidney might have been repaired or the lower part resected were it not that an attempt to deliver the kidney outside the wound showed it was not going to be an easy matter, that the extravasated blood and urine were welling up to obstruct our view, that there was considerable active hemorrhage from the kidney, and that our anesthetist warned us that the patient's pulse was getting bad. We decided that the quickest procedure would be the least risky and removed the kidney.

A cigarette drain was placed in the wound, this closed in layers, and the patient was put to bed on the affected side. The drain and the skin stitches were removed in forty-eight hours. The patient's convalescence was uninterrupted.

## A NEW METHOD OF TREATING THE TOXEMIA OF PREGNANCY

PRELIMINARY COMMUNICATION.

By GEORGE P. SHEARS, M.D.,

NEW YORK.

ATTENDING OBSTETRICIAN, CITY, POLYCLINIC, AND MISERICORDIA HOSPITALS.

Zweifel has aptly called puerperal eclampsia the disease of theories. This designation would apply with equal force to the toxemia of pregnancy since this is usually, if not invariably, the precursor of eclampsia. At present the most commonly accepted hypothesis is that the offending agent is elaborated in the processes of fetal and placental metabolism.

Perhaps the most significant and encouraging studies have been those made in connection with the now familiar "nitrogen partition," which have shown that nitrogenous substances are excreted by the kidneys in a state of incomplete oxidation. Various observers have endeavored to find the toxin in some imperfectly oxidized body, *e.g.* lactic acid, but these efforts have been barren of results. So many skilled observers in all parts of the world have been working in this field that it seems difficult to believe that any specific poison could have escaped observation.

May it not be that we have been looking too far for the cause of the symptom-complex, which we call the toxemia of pregnancy, but which should be called the pre-eclamptic condition? In other words, may not suboxidation itself be the real cause, or, at all events, a prominent factor? In pregnancy a woman needs oxygen more than at any other time. The clinical symptoms, from the subjective dyspnea, so common in pregnancy approximately normal, to the headache, edema, and final convulsions of profound toxemia, are strongly suggestive of lack of oxygen. This theory helps to explain why eclampsia occurs so often in robust and vigorous young women. These patients have a high oxidative equilibrium and are the first to suffer from oxygen deficiency.

Acting upon this theory, I have recently treated my toxemic cases by the free use of oxygen. Most of these cases were seen in my service at the City Hospital and four of them were of the severe type. Improvement and eventual recovery were noted in all. In one, that of a very intelligent patient, the relief afforded was so prompt and complete that it seemed difficult to ascribe it to mere coincidence.

I hope to give at some future time a detailed report of the above cases. Of course the number

is too small to enable one to draw positive conclusions. Perhaps some of my colleagues may be led to test this method. It can do no harm and will be found subjectively agreeable to the patient. Meanwhile I would suggest the free use of oxygen, either by inhalation or subcutaneously. This method of treatment in no way conflicts with milk-diet, catharsis, hydrotherapeusis, and other curative agents of proved efficiency.

I have found no reference either in English, French, or German, to the use of oxygen in the toxemia of pregnancy. It is true that oxygen has been used empirically in the cyanosis and respiratory obstruction that characterize the convulsions of eclampsia, but that is quite a different matter. . . . Since the above was written my attention has been called to the experiments of Healy and Kastle in connection with the so-called parturient paresis of cattle, which bears a remarkable clinical and pathological resemblance to eclampsia. Believing the disease to be of mammary origin, they report a remarkable series of cures *by the injection of the udders with oxygen.* This would seem to afford striking confirmation of the theory which I have ventured to advance.

203 West One Hundred and Third Street.

## REPORT OF A CASE OF SINUS THROMBOSIS; OPERATION; RECOVERY.*

By I. GRUSHLAW, M.D.,

NEW YORK.

VISITING OTOLOGIST AND LARYNGOLOGIST, THE PEOPLE'S HOSPITAL ADJUNCT OTOLOGIST AND LARYNGOLOGIST, THE LEBANON HOSPITAL; LECTURER ON DISEASES OF THE NOSE AND THROAT, THE NEW YORK POLYCLINIC.

Bene F., 18 years old, buttonhole maker by occupation, was admitted to the People's Hospital on March 18, 1911. He gave a history of pain in the ear for which a myringotomy had been done, which relieved him. Physical examination showed a fairly nourished young man. The heart, lungs, and kidneys were normal. As his temperature on admission was only 99.4° and he felt fairly well, he was treated as a simple case of acute purulent otitis media, by hot-water bag and irrigations of 1-5000 bichloride solution. On the 19th his temperature rose to 101° and went down to 99.2° on the 20th. On the 21st the temperature rose to 106.4°, pulse 140, respiration 28, and he complained of considerable pain.

I saw him for the first time on the 21st, when he gave the impression of being very sick. On examination, I found his ear draining well, and there was no bulging or sagging of the posterior and superior canal walls. The drum membrane had a large perforation and the appearance was that of a mild cases of acute otitis media purulenta. There was only slight pain on deep pressure over the tip and antrum. As there were hardly any signs of mastoiditis, every other cause had to be excluded before an exploratory mastoidectomy could be decided upon. The patient was carefully examined and absolutely nothing but the ear condition was found to account for it. The blood count showed 14,800 leucocytes with 84 per cent. polynuclears. I determined to explore the mastoid.

*Operation.*—An incision was made from above the auricle and ½ cm. posteriorly down to the tip of the mastoid process. On elevating the periosteum, the cortex was found normal. On removing the cortex with gauze and mallet, I found extensive necrosis; the cells were filled with granulations and pus. The antrum was but slightly involved; the tip, on the other hand, was all diseased. The fact that the antrum was but little involved may explain the absence of signs in the middle ear. I removed the mastoid tip and all the diseased bone by rongeur and curette, until healthy bone was reached. By so doing I exposed the sigmoid sinus, which looked rather healthy, trusting that the mastoidectomy would prevent the thrombus should the sinus contain one, from becoming septic, I left it alone and packed the cavity with iodoform gauze.

On March 22 the temperature was 102°, pulse 120. The patient was comfortable and had no pain. On March 23 the temperature was 105.2°, pulse 130. Patient had a slight chill with severe headache and talked irrationally during the night. The wound was dressed and found clean. I suspected a septic thrombus in the lateral sinus, but owing to the fact that the sinus looked perfectly normal, I determined to wait another twenty-four hours. A blood culture was made and found negative.

March 24.—Temperature 103.2°, pulse 110, severe headache; patient very sick. In view of the sudden rise in temperature, chills, and no marked improvement occurring for three days, I decided to explore the sinus.

*Operation.*—I removed the bone from the sinus, thus exposing it for 1½ inches. I had my assistant apply pressure to the torcular and jugular ends of the sinus by inserting two small plugs of gauze between the cortex and the sinus wall. A long incision was made in the middle of the sinus which contained a large thrombus. On account of free bleeding from the jugular end, I had to insert another plug. The thrombus seemed to be broken down in the middle and fairly firm at both ends. I curetted the sinus as far as possible, and kept it up until free bleeding occurred from the torcular end. As there was no apparent involvement of the internal jugular and it bled freely from the jugular end, I determined not to ligate the jugular unless there should be further trouble. The sinus was then packed.

On March 25 the temperature was 98.2° in the morning, pulse 96. Patient passed a comfortable night, very weak, but feels much better. Twelve P.M. had slight chill and temperature rose to 102.2°. On March 26 temperature in the morning was 99°. Packing removed. Patient very much improved. Eight P.M. temperature rose to 103.8°, probably due to dislodgment of the clot by removing the packing.

On March 27 the temperature was 102°, pulse 120. Patient anemic, but otherwise feeling and looking well. The patient was discharged from the hospital on April 10, almost cured, and then made an uneventful recovery.

The interesting features of the case are:

1. The normal appearance of the sinus, although the seat of a septic thrombus.
2. The extensive involvement of the sinus with hardly any signs.
3. Recovery, although the jugular was not ligated.
4. The mastoid was diseased without giving rise to any signs whatsoever.
5. The severe infection followed a slight operation on the nose which had been performed in some dispensary.

1855 Seventh Avenue.

## THE PERENNIAL PROBLEMS OF PNEUMONIA.

THE season of greatest prevalence of pneumonia is close at hand. The manifold problems which are presented by this disease continue to challenge the attention of laboratory workers and clinicians. The subject is so large that only its outposts have been sighted by the vanguard of modern investigation. The complexity of the factors that enter into the production of pneumonia—the factor of bacterial virulence, the factor of the relative resistance of human beings and of animals to infection, the factor of individual resistance among human beings, and the factor of climate—this complexity imparts to the study of pneumonia an interest that is not surpassed in the case of any other disease.

A valuable clinical study of certain atypical forms of pneumonia is contributed to the *Zeitschrift für klinische Medizin*, Vol. 76, Nos. 5 and 6, by A. Austregesilo of Rio de Janeiro. In that city, whose distance from the equator is the same as that of Havana, it has long been thought that genuine pneumonia is rare. The above observer, who occupies the chair of medicine in Rio de Janeiro, notes however that the classical type of pneumonia prevails in this tropical city, but not to the same extent as in Europe. On the other hand the atypical cases exceed in number those that follow the normal course. Of the former there are distinguished two varieties which are designated "pneumonia abortiva" and "pneumococcia thoracica bastarda." It is pointed out that the various clinical manifestations of pneumonia as observed in Rio depend less upon the individual's resistance than upon the varying virulence of the pneumococcus.

The abortive type of pneumonia has been described by clinicians in different parts of the world. It is the pneumonia of one to three days' duration described by Osler under the term "larval pneumonia," in which apparently the activity of the pneumococcus is exhausted during the stage of engorgement. In these cases, the invasion and clinical manifestations of which differ in no respects from those of the typical cases, there may or may not appear the characteristic physical signs of pneumonia; there may be in fact "eine wahrhafte Pneumonie ohne Pneumonie."

The so-called "forme fruste" or "pneumonia bastarda" is closely allied to the abortive type, but it has certain distinctive characteristics. The disease begins with the severe chill and the pain in the side which are characteristic of the usual form of pneumonia. There then set in the symptoms which are peculiar to these pseudopneumonias, namely, an obstinate and severe cough, a more or less pronounced dyspnea, and the appearance on the second or third day of a tenacious and blood-tinged sputum which is loaded with pneumococci. The physical signs are indefinite during the first thirty-six hours. There are then made out areas of slight dullness over the lower lobes, and exceptionally over the upper lobes. The bronchial breathing and the râles appear distant and indistinct. The general symptoms of the disease are severe. The course is a short one and resolution occurs by lysis. Pleural complications are almost constant, and finally dominate the clinical picture.

Austregesilo takes issue with the French school who describe primary idiopathic congestions of the lung and regard these as distinct clinical entities. He believes that in these cases there is an underlying inflammation of the lung parenchyma with an accompanying inflammation of the pleura, and that the congestion is only incidental to the pneumococcus infection. Nevertheless the French clinicians, who more than any other have paid considerable attention to this subject, have described seven different forms of primary pulmonary congestion, as follows: (1) the acute pulmonary congestion or so-called *maladie de Woillez;* (2) the catarrhal congestion of the thoracic organs described by Dupré, Grasset, and Dieulafoy; (3) the pleuropulmonary congestion of Potain and Serrand; (4) the pneumonia splenica of Grancher and Queirat; (5) the pulmonary apoplexy, the paroxysmal congestion of Weill, and the bronchoplegic congestion of Huchard; (6) the pulmonary congestion without sputum, and the dry pneumonia of Wiedmann; and (7) the protracted pulmonary congestion of Renon. Austregesilo believes that all of these forms correspond to the "pneumococciæ thoracicæ bastardæ." Two types stand out with greatest prominence: the type of Woillez, in which the pulmonary parenchyma and to a less extent the pleura are involved; and the type of Potain, in which the pleural manifestations predominate. It appears as if in these cases the pneumococcus does not produce the inflammation characteristic of its invasion of the lungs. It causes congestion and inflammation but without any marked hepatization. This is not an abortive pneumonia; it is rather an abnormal pneumonia, with or without involvement of the pleura.

With the increasing recognition of pneumococcus infections of different organs of the body there has at the same time developed a conception that pneumonia, unlike typhoid fever, is a local process, and not a septicemia. Nevertheless, employing improved cultural methods, G. Jochmann ("Handbuch der inneren Medizin," 1911), has been able to demonstrate the presence of pneumococci in the blood in 70 per cent. of his cases of pneumonia. If the number of bacteria in the blood is not large, and if these do not give rise to any special symptoms, the condition is regarded by Jochmann as one

of pneumococcus bacteriemia, which in no respect darkens the prognosis. On the other hand if the blood is invaded with a large number of these microorganisms, which then give rise to pronounced clinical symptoms, such as a continued high fever, and the development of an endocarditis, joint metastases, etc., then the condition must be regarded as one of pneumococcal sepsis, and the prognosis is correspondingly a much more serious one.

The solution of the intricate problems of pneumonia is closely bound up with the question of the varying virulence of the pneumococci. This phase of the subject forms the title of a thesis by L. Cotoni.* This observer studied the virulence of pneumococci obtained from cases of pneumonia in human beings and injected into rabbits, mice, and guinea-pigs. He found that there is no necessary relationship between the gravity of a case of pneumonia and the virulence of the infecting germs. Nevertheless, if the microorganisms manifest a high degree of virulence for the mouse, and still more so for the rabbit and guinea-pig, this fact constitutes a strong presumption in favor of the pronounced activity of these bacteria in the human organism. With the virulence of a certain strain of pneumococci for animals it is possible to compare the gravity of the human infection caused by the same strain, and not the virulence of this strain in human beings. The latter is a quantity impossible to measure, for the resistance of the host is an unknown quantity, and the number of invading microorganisms cannot be estimated. Moreover the definite anatomical lesions in the lungs in the case of the overwhelming majority of the human infections, form a sharp contrast to the experimental septicemia of mice.

Fortunately the modern studies of pneumonia are not being conducted exclusively in the laboratory. Mankind is on the defensive against the pneumococcus, and the plans of warfare are being drawn with almost military precision. The high mortality from pneumonia among the native laborers in the Transvaal mines is engaging the attention of Sir Almroth E. Wright and his associates, and the first part of their report has recently been published in the *Lancet,* December 14 and 21, 1912. (See MEDICAL RECORD, January 4, 1913, page 31, and also this issue, page 77). This communication is concerned chiefly with the results of the investigation of the therapeutic value of Morgenroth's drug, ethylhydrocuprein hydrochlorate, in pneumonia. While it is shown that this substance exerts a bactericidal effect specifically upon the pneumococcus, it is at the same time not devoid of toxic action upon the human organism. Its neurotropic effect has been manifested in the relatively large number of cases of amblyopia which have resulted from the use of this drug. One may cherish the hope that as in the case of the organic arsenic derivatives, it will be possible in the future developments of synthetic chemistry, to eliminate in great part the organotropic property and at the same time to preserve or even increase the parasitotropic action of Morgenroth's drug.

*"La Virulence des Pneumocoques," par L. Cotoni, Ancien Interne des Hôpitaux de Paris. Thèse pour le Doctorat en Médecine. Paris: G. Steinheil. 1912.

## A CELL PROLIFERANT.

IN the older pharmacy, long before the day of the aseptic treatment of wounds, much account was made of vulneraries. Friar's balsam, basilicon ointment, balm of Gilead, balsam of Peru, comfrey, turpentine, and a host of other remedies were vaunted for their healing virtues. Some doubtless acted through what we now recognize as their antiseptic properties, while others certainly possessed a power of accelerating cell growth. Among the latter was comfrey, the root of which was in frequent use by the ancient leeches not only as a healer of wounds of the soft parts and an accelerator of union of fractured bones, but as a soothing remedy in certain gastric disorders, probably ulcer. This drug, which has always retained its repute as a vulnerary in domestic practice, was not long ago studied both clinically and chemically by Macalister (*Liverpool Medico-Chirurgicol Journal,* January, 1912), who found its healing properties to reside in a crystallizable principle, glyoxyldiureide, or allantoin. This substance is found not only in the growing parts—buds, bark of the twigs, etc.—of comfrey and other plants, but also in the allantoic and amniotic fluids and in the urine of infants and pregnant women, only traces or none at all being excreted in the urine of adult man. It is thus seen to be associated with the process of growth in both plants and animals. Clinically, Macalister, Bramwell, Murray, and others (*British Medical Journal,* January 6 and 13, 1912) found an extract or paste of comfrey root, and especially a solution of allantoin derived therefrom, remarkably efficacious in promoting epithelial growth. Sluggish ulcers, which had long resisted treatment, healed rapidly under applications of this substance, and fistulæ of long standing also closed promptly after the insertion of gauze wicks impregnated with the solution.

It is interesting in this connection to note the results obtained by Carrel (*Journal of Experimental Medicine,* January, 1913) in the activation of the growth of connective tissue *in vitro* by means of the addition of tissue juices. He made a number of experiments to determine the comparative growth of cells placed in normal plasma and in plasma containing an addition of a tissue juice. All the tissue juices accelerated the growth of connective-tissue cells, but the degree of acceleration varied greatly according to the tissue from which the extract was made. Embryonal tissue extract was the most active, and nearly as potent were extracts of adult spleen and of Rous sarcoma tissue. Extracts of the kidney and heart were less active, and least of all were extracts of connective tissue and of blood corpuscles. Carrel studied the effect of heating, of filtration, and of concentration upon the activity of the tissue juices employed, but he gives no account of any chemical tests to determine the nature of the activating agent. It is interesting, however, to note that the really potent extracts were those made from embryonic and actively growing tissues, the same indeed as those in which allantoin is found most abundantly. A common ingredient of many of the ancient vulneraries, and of some of those in popular vogue to-day, was urine, especially the urine of a

young child, which contains allantoin. It would be interesting to determine whether this excretion would act, like the tissue juices, as an accelerator of cell growth *in vitro*.

### A Neurologist on Freud's Theories.

The dissemination of Freud's theories has brought out a great deal of what seems to be to some extent partisanship on the part of neurologists. While his views have somewhat the effect of a red rag to a bull on some neurologists, by his adherents they appear to be regarded as almost sacred. Of course, the heated discussions which have taken place with regard to the Freudian dicta have had something to do with the attitude assumed by pro-Freudians. For, after all, it is only natural that when theories in which a man believes are sharply assailed they should be as strongly defended. Of course, to the ordinary individual and even to the practitioner not skilled or deeply read in neurology, the statements made by Freud as to the influence of sexual instincts on the origin and causation of neuroses savor of gross exaggeration. But even to many neurologists who freely allow that such instincts are factors in the production of neuroses, it nevertheless appears evident that Freud and his disciples have overstated their case and carried their theories to an almost absurd length. In this country Starr and others have dissented from Freud's views on more than one occasion, and in Europe several of the most renowned nerve specialists have argued more strongly by far against their acceptance. At a meeting of the Swiss Society of Neurology which took place at Lucerne on November 9 and 10, an account of which is given in the *Lancet*, November 23, 1912, Professor Ladame of Geneva in a report on neuroses and sexuality gave a complete résumé of Freud's theories. He pointed out that Crämer, Löwenfeldt, and Oppenheim have seriously opposed the theory of pan-sexuality and that quite a number of other authors have combated what they believed to be exaggerated and inexact views. Kurt Mendel wrote a biting satire on Freud's typical infant, whose suction of the thumb and childish sports were referred exclusively to the sexual sphere. As for the dangers of sexual abstinence, so strongly dwelt upon by Freud, in the opinion of Ladame those dangers are nonexistent. Ladame considered that a capital mistake had been made in confounding the functions of nutrition and those of reproduction.

### Causes of Falling Birth Rate in Germany.

It is pretty generally held, we believe, that the falling birth rates of the culture countries are due chiefly to deliberate refusal to propagate the species rather than to a falling off in the marriage rate and sterility in male or female, although doubtless both these factors must enter to some extent into a consideration of the causes, for both combined would fail to produce such diminutions of birth rate as are constantly coming to light. This is the conclusion of Gummert, expressed recently before a medical society in Essen-Ruhr (*Berliner klinische Wochenschrift*, November 25). Prevention of conception, which was once the privilege of the rich, has now descended by degrees to the poor, so that it has become universal. The evidence that this is the chief cause of the falling birth rate is seen in the enormous number and variety of preventive resources, and in the greatly increased proportion of abortions to conceptions. The only solution of the problem is a campaign against the criminal interruption of pregnancy; for the prevention of conception can hardly be reached by law. In Austria abortion is now placed among reportable affections, but this is regarded as an attack on personal liberty. In the absence of any dominant principle in conducting a crusade, the latter can be carried out only piecemeal. For example, peddlers hawk from house to house syringes intended to prevent conception although ostensibly recommended for cleanliness or comfort. It might be possible to secure some restrictive legislation against this instrument. Among facts brought out in the discussion of this paper, it was interesting to learn that the illegitimate birth rate does not suffer like the legitimate; that the Roman Catholic Church is no longer a bulwark against the prevention of conception, and that abortions are rare among the poor because abortionists work solely for gain, and in a criminal calling one would not expect anything else of them.

### Latent Erysipelas.

The use of the term latent as applied to diseases appears to differ considerably with the nature of the latter. In general it should mean that there is some evidence of the presence of a given affection in the absence of its usual manifestations. More or less confusion must arise between such terms as "latent," "occult," "cryptic," "masked," "equivocal," and the like, so that the custom of using these adjectives is one of questionable value. At a recent meeting of the Berlin Surgical Society (*Berliner klinische Wochenschrift*, December 2) Schlesinger reported two cases of what he styled "latent erysipelas." The characteristics appear to have been a prolonged incubation period and deep initial manifestation which involved the skin eventually. In one case a nurse was scratched on the back of the hand by a septic patient. The wound healed, and not until after two weeks did symptoms appear which suggested periostitis of the ulna. Meanwhile a neurologist had diagnosticated neuralgia. Eventually erysipelas appeared over the ulna and involved the entire limb, trunk, and head. The other case was similar in character, but followed an operation. The author appears to regard such cases as equivalents of phlegmonous processes, in which pus slowly forms and first manifests itself at a period remote from the date of infection. While the incubation period of ordinary erysipelas should not exceed eight days, in these cases three weeks and two months respectively elapsed between the act of infection and the first appearance of the erysipelatous blush.

### Cacoethes Investigandi.

Senator Gore of Oklahoma has announced his intention of introducing into the Senate a resolution directing a full investigation by the United States Government of the alleged cure of cases of tuberculosis said to have been effected by Dr. Friedmann of Berlin. We can think of at least five hundred ways in which the money of the United States can be spent to better advantage than in investigating a secret "consumption cure." Dr. Friedmann's colleagues in Berlin can be trusted to do that effectively without the aid of the United States Senate.

## News of the Week.

**Tuberculosis Fight in 1912.**—During the year just completed nearly $19,000,000, according to the figures of the National Association for the Prevention of Tuberculosis, was spent in the United States in the fight against this disease, the total being nearly $5,000,000 in excess of the expenditures for 1911. More than a quarter of this amount was raised in New York State alone, the contributions from the leading States being as follows: New York: Public, $3,805,556; private, $1,356,760; total, $5,162,316. Pennsylvania: Public, $1,587,596; private, $632,231; total, $2,219,827. Massachusetts: Public, $1,064,905; private, $342,414; total, $1,407,319. For the maintenance and establishment of open-air schools and classes, over $115,000 was expended; the dispensaries and tuberculosis clinics spent about $560,000, and the anti-tuberculosis associations and committees about $765,000. Nearly $17,000,000 was devoted to sanatorium and hospital construction and treatment. In addition about $500,000 was spent in caring for tuberculous patients in hospitals for the insane and penal institutions.

**New York's Vital Statistics.**—For the week ending December 28 the total number of deaths in New York City was 1,636, an increase of 141 over the previous week. In Manhattan Borough alone the death rate was 16.20 per thousand, as compared with 14.46 for the same week of last year. In the other boroughs, however, the rate was decreased. The statistics for the year 1912 show a total of 73,008 deaths in New York City, a decrease of 2,415 as compared with 1911, the death rate for the year being 14.11 per thousand of population, the lowest on record. For 1911 the rate was 15.13, for 1910, 15.98, and for 1909, 16. A comparison of the statistics shows a reduced mortality in all causes except cancer and homicide, as well as a large decrease in the number of deaths reported in tenement houses. The infant mortality during the year was the loweest ever recorded in the city, 14,289 deaths being reported, and the rate of 10.05 is lower than that of any other large city with the exception of Paris. The births during 1912 numbered 135,625, which is an absolute increase of 1,083 over 1911, though the birth rate for the year, 26.22, is the lowest since 1906. The marriage rate, however, was the highest in five years, 52,391 having been reported.

**Russia's Death Rate High.**—Reports from Russia state that the mortality in that country has increased in the last five years from 28 to 31 per thousand, giving it probably the highest death rate in the world. Severe epidemics, mainly of typhoid fever, are responsible for the high mortality.

**Jewish Maternity Hospital.**—The report of this institution for the past year gives the number of births within its walls as 1,162, including fourteen sets of twins and one set of triplets. The number of males born exceeded the females by 51.

**Street Accidents.**—During 1912, there were 532 persons killed in accidents on the streets of New York City, 230 of these being children. The total number of persons injured was 2,363. Accidents on streets and highways throughout the State caused the death of 234 persons, while in railroad grade crossing accidents 107 persons were killed and 127 injured. There was an increase of 38 per cent. in automobile accidents.

**Stops Ambulance Service.**—The Presbyterian Hospital, New York, after maintaining an ambulance service for thirty-two years, temporarily discontinued it on January 1. The reason given is that the Hospital is preparing to move from its present quarters and can not maintain an efficient service while doing so. It is expected that the service will be resumed later, and in the meantime the district will be covered by the Flower Hospital.

**Harvey Society Lecture.**—The sixth lecture of of the Harvey Society for this season will be delivered by Major J. J. Russell, U. S. A., at eight-thirty on Saturday evening, January 18, at the New York Academy of Medicine. The subject of the lecture will be: "The Prevention of Typhoid Fever."

**"Typhoid Mary" Loses.**—Mary Mullen, known to medical circles as "Typhoid Mary," has been advised that she has no cause of action against the Board of Health of New York, or against Commissioner Lederle, Dr. Bensel, or Dr. Soper, who caused her to be detained for three years on North Brother Island as a public menace. The Board of Health in this case, it is held, acted entirely within the power conferred upon it by the city charter.

**Personals.**—Dr. Charles Milton Ford of New York, for many years attending surgeon to the New York City Children's Hospitals and Schools, Randall's Island, has recently been appointed consulting surgeon to these institutions.

Dr. William W. Smithson of Jackson, Miss., has been appointed superintendent of the Mississippi State Hospital for the Insane.

Mrs. Elimina K. Spencer, a veteran army nurse, who served through the Civil War with the 147th New York Volunteers, died at her home in Oswego on December 29, at the age of 94 years.

**British Physicians Accepting Service under the Insurance Act.**—The physicians in Great Britain have apparently decided to abandon their fight against the Government and the new Insurance Act, and on January 3 close to 10,000 of them had accepted service under the Government's terms. The Medical Benefit Act is scheduled to go into operation on January 15.

**Dies at 105.**—Mrs. Mary Ann Peterson of New London, Conn., died there recently in her 106th year.

**Bellevue Hospital Library.**—The Medical Superintendent of Bellevue Hospital announces that the library connected with the Pathological Department of the new Bellevue Hospital, at Twenty-ninth street and First avenue, is open for the use of all practising physicians.

**Health of the Canal Zone.**—For the month of October, 1912, the death rate among employees in the Canal Zone was 9.10 per thousand, the lowest rate on record for the month. The total number of deaths was thirty-eight, of which twenty-eight were due to disease. Among the entire civil population the death rate was 23.08 per thousand. Eight deaths were due to tuberculosis, four to pneumonia, one to malaria, and ten to external violence. There were no cases of yellow fever, smallpox, or plague.

**Grading of Milk.**—The New York City Department of Health recently issued a circular describing the present plan of marking milk sold in the city. Grade A milk comprises all milk suitable for the use of infants and children, and is sold only in bottles. Grade B milk is that suitable for adults, comprising Pasteurized milk and selected raw milk, and is sold in bottles or cans. Grade C milk is that suitable for cooking purposes only and is the poorest grade permitted to be sold. The bottles and

cans must be clearly labeled to indicate to what grade the contents belong, the markings for each grade being of a distinctive color. Pasteurized milk also must be plainly marked. Only Grade A and Grade B milk are allowed for sale by restaurants, lunch counters, etc., for immediate use by adults, and it is recommended that Grade A milk only be used for children. Pasteurized milk is considered by the department to be safer than raw milk of the same grade.

**State Board Examinations.**—Of 110 applicants who appeared recently before the Pennsylvania State Bureau of Medical Education and Licensure, only seventy received licenses to practise in the State. Forty failed to secure the necessary average marks.

**Civil Service Examinations.**—The United States Civil Service Commission will hold an examination on January 22, 1913, for the purpose of filling a vacancy in the position of medical interne in the Government Hospital for the Insane at Washington, at $1,600 per annum and maintenance, and other vacancies as they may occur in positions requiring the same qualifications. The examination will be open to both men and women although at present there are no vacancies for the latter. Candidates must be unmarried, twenty years of age and over, and citizens of the United States. The Government Hospital for the Insane houses over 2,900 patients and about 750 employees.

On February 5, 1913, an examination will be held for the purpose of filling vacancies in the Indian Service at the following places: Navajo Agency, $1,000 per annum; Cheyenne River Agency, S. D., $1,000; Santee Agency, Neb., $1,000; Western Navajo Agency, Ariz., $1,200. Only men physicians or members of graduating classes in recognized medical schools will be admitted to this examination. Full particulars as to both examinations may be obtained from the United States Civil Service Commission, Washington, D. C.

**Associated Out-Patient Clinics.**—The final organization of this association has been effected with Mr. George L. Rives as president, Mr. H. S. Van Duzer, Dr. Gorham Bacon, and Dr. J. W. Brannan, as vice-presidents, and Dr. S. S. Goldwater, as secretary and treasurer; an investigation of the existing dispensary facilities has been begun, and the association will soon spread to the other boroughs of the city. A contribution of $5,000 has been made recently for the organization work.

**Historical Medical Exhibition.**—In connection with the meetings of the International Medical Congress in London next summer, an exhibition of rare and curious objects relating to medicine, chemistry, pharmacy, and allied subjects is being arranged by Mr. Henry S. Wellcome. Among the interesting exhibits will be a section devoted to the medical deities of savage and barbaric peoples; and amulets, talismans, and charms connected with the art of healing will form another feature. In the section on surgery the evolution of surgical instruments will be traced from the earliest times; and relics of alchemy will also be shown. Loans of all such objects will be gratefully received by the secretary, who may be addressed as 54a Wigmore street, London, W.

**Welfare of Infancy.**—A movement in England, similar to that in this country, has resulted in an alliance among a number of associations interested in the welfare of infants, and the formation of a National Association for the Prevention of Infant Mortality, of which their Majesties the King and Queen have consented to act as patrons. Mr. John Burns is the president of the association, and plans are being made for an English-speaking conference on infant mortality to be held in London on August 4 and 5, immediately preceding the meetings of the International Medical Congress.

**Health Legislation.**—The American Association for Labor Legislation proposes as a part of its legislative program for 1913, the passage of laws designed to prevent lead poisoning in this country. Cleanliness of workrooms and workers and the use of hoods and exhausts to eliminate fumes and lead dust will, it is believed, accomplish this end. The association also includes in its program the securing of a one-day-rest-in-seven law, a Federal compensation act, and laws for the protection of working women.

**Society of American Bacteriologists.**—The meeting held in New York, December 31, 1912, and January 1 and 2, 1913, was one of the most successful the society has ever had, both in general interest, as evidenced by the large attendance at each session and in the importance of the papers presented. The following officers were elected: *President,* Prof. C. E. A. Winslow, American Museum of Natural History, New York City; *Vice-President,* Prof. Chas. E. Marshall, Massachusetts Agricultural College, Amherst, Mass.; *Secretary-Treasurer,* Dr. A. Parker Hitchens, Glenolden, Pa.; *Council,* W. J. MacNeal, L. F. Rettger, D. H. Bergey, H. A. Harding; *Delegate to Council of American Association for the Advancement of Science,* Prof. S. E. Prescott.

**Medical Society Elections.**—Mobile County (Ala.) Medical Society: Annual meeting at Mobile on December 7. Officers elected: *President,* Dr. R. H. von Ezdorf, U. S. Marine-Hospital Service; *Vice-President,* Dr. R. A. Wright; *Secretary,* Dr. W. W. Scales; *Treasurer,* Dr. E. S. Sledge.

North Central Illinois Medical Society: Annual meeting at Pontiac on December 4. Officers elected: *President,* Dr. Ezra T. Goble, Earlville; *Vice-Presidents,* Dr. C. C. Hunt, Dixon, and Dr. C. D. Thomas, Peoria: *Secretary-Treasurer,* Dr. George A. Dicus, Streator.

Parker-Palo Pinto County (Tex.) Medical Society: Annual meeting at Weatherford on December 10. Officers elected: *President,* Dr. J. H. Eastland, Mineral Wells; *Vice-President,* Dr. J. H. McCorkle, Gordon; *Secretary-Treasurer,* Dr. J. H. McCracken, Mineral Wells; *Censor,* Dr. B. R. Beeter, Mineral Wells.

Vermilion County (Ill.) Medical Society: Annual meeting at Danville on December 9. Officers elected: *President,* Dr. Frank M. Mason, Rossville; *Vice-President;* Dr. H. F. Dice, Ridgefarm; *Secretary-Treasurer,* Dr. Solomon Jones, Danville; *Censor,* Dr. O. H. Crist, Danville.

El Paso County (Col.) Medical Society: Annual meeting at Colorado Springs on December 11. Officers elected: *President,* Dr. Beverley Tucker, Colorado Springs; *Vice-President,* Dr. George A. Boyd, Colorado Springs; *Secretary,* Dr. James H. Brown, Colorado Springs; *Treasurer,* Dr. G. B. Gilmore, Colorado City.

Greene County (Ind.) Medical Society: Annual meeting at Linton on December 12. Officers elected: *President,* Dr. Frank A. Van Sandt; *Vice-President,* Dr. Charles D. Mallett of Switz City; *Secretary-Treasurer,* Dr. T. Roy Cook, Bloomfield.

Bartholomew County (Ind.) Medical Society:

Annual meeting at Columbus on December 10. Officers elected: *President,* Dr. Richard E. Holder, Columbus; *Vice-President,* Dr. James W. Benham, Columbus; *Secretary,* Dr. Elmer U. Wood, Columbus.

Mills County (Ia.) Medical Society: Annual meeting at Glenwood on December 5. Officers elected: *President,* Dr. George M. Agan; *Vice-President,* Dr. Roy Moon, Glenwood; *Secretary-Treasurer,* Dr. J. M. Donelan, Glenwood.

Androscoggin County (Me.) Medical Society: Annual meeting at Lewiston on December 3. Officers elected: *President,* Dr. W. L. Haskell, Lewiston; *Vice-President,* Dr. Joseph W. Scannell; *Secretary-Treasurer,* Dr. S. E. Sawyer, Lewiston.

Portland (Me.) Medical Association: Annual meeting at Portland on December 5. Officers elected: *President,* Dr. Harold A. Pingree; *Vice-Presidents,* Dr. Walter D. Williamson and Dr. Alfred Mitchell, Jr.; *Secretary-Treasurer,* Dr. Roland B. Moore.

Southern Minnesota Medical Association: Annual meeting at Mankato on December 4. Officers elected: *President,* Dr. Allan B. Stewart, Owatonna; *Vice-Presidents,* Dr. A. G. Liedloff, Mankato, and Dr. W. J. Richardson, Fairmont; *Secretary,* Dr. A. F. Adams, Elgin; *Treasurer,* Dr. George F. Merritt, St. Peter.

Harrison County (Miss.) Medical Society: Annual meeting at Gulfport on December 2. Officers elected: *President,* Dr. A. F. Caraway, Gulfport; *Vice-President,* Dr. B. F. Welch; *Secretary-Treasurer,* Dr. Daniel J. Williams, Gulfport.

Tri-County (Miss.) Medical Association: Annual meeting at Brookhaven on December 3, with many delegates from Pike, Lincoln, and Copiah Counties. Officers elected: *President,* Dr. W. D. Beachman, McComb; *Vice-Presidents,* Dr. J. M. Catchings, Copiah County; Dr. O. N. Arrington, Lincoln County, and Dr. T. K. Magee, Pike County; *Secretary-Treasurer,* Dr. D. W. Jones, Brookhaven.

Cape County (Mo.) Medical Society: Annual meeting at Cape Girardeau on December 9. Officers elected: *President,* Dr. Elisha H. G. Wilson, Cape Girardeau; *Secretary,* Dr. Daniel H. Hope, Cape Girardeau.

St. Joseph-Buchanan-Andrew Counties (Mo.) Medical Society: Annual meeting at St. Joseph on December 4. Officers elected: *President,* Dr. Albert L. Gray, St. Joseph; *Vice-Presidents,* Dr. Arthur B. McGlotham, St. Joseph, and Dr. Floyd H. Spencer, St. Joseph; *Secretary,* Dr. William F. Goetze, St. Joseph; *Treasurer,* Dr. John M. Bell, St. Joseph.

Audrain County (Mo.) Medical Society: Annual meeting at Mexico on December 2. Officers elected: *President,* Dr. John F. Harrison, Mexico; *Vice-Presidents,* Dr. R. W. Berry, Mexico, and Dr. R. T. Gibbs, Mexico; *Secretary-Treasurer,* Dr. Robert C. Strode, Mexico.

Wake County (N. C.) Medical Society: Annual meeting at Raleigh on December 13. Officers elected: *President,* Dr. H. A. Royster; *Vice-President,* Dr. W. T. Carstarphen; *Secretary,* Dr. W. C. Horton; *Treasurer,* Dr. K. P. Battle, Jr.

Wilson County (N. C.) Medical Society: Annual meeting at Wilson on December 4. Officers elected: *President,* Dr. M. M. Saliba; *Vice-President,* Dr. C. L. Swindell; *Secretary-Treasurer,* Dr. K. C. Moore.

Seaboard Medical Association: Annual meeting at New Bern, N. C., on December 3 to 5. Officers elected: *President,* Dr. L. E. Rawls, Suffolk, Va.; *Vice-Presidents,* Dr. H. D. Walker, Elizabeth City, N. C.; Dr. B. R. Kennon, Norfolk; Dr. Joshua Tayloe, Washington, N. C.; Dr. G. K. Vanderslice, Phoebus; *Treasurer,* Dr. Israel Brown, Norfolk; *Secretary,* Dr C. P. Jones, Newport News, Vt.

Lorain County (O.) Medical Society: Annual meeting at Elyria on December 10. Officers elected: *President,* Dr. J. B. Donaldson; *Vice-President,* Dr. C. P. Clements; *Secretary,* Dr. W. S. Baldwin; *Treasurer,* Dr. Evan Cameron.

Darke County (O.) Medical Society: Annual meeting at Greensville on December 12. Officers elected: *President,* Dr. J. O. Starr, Pittsburgh; *Vice-President,* Dr. Donovan Robeson, Greensville; *Secretary-Treasurer,* Dr. J. E. Hunter, Greensville.

Grady County (Okla.) Medical Society: Annual meeting at Chickasha on December 6. Officers elected: *President,* Dr. Walter Penquite; *Vice-Presidents,* Dr. R. P. Tye and Dr. L. H. Winborn; *Secretary,* Dr. Martha Bledsoe.

Kent County (R. I.) Medical Society: Annual meeting at East Greenwich on December 12. Officers elected: *President,* Dr. Ira D. Hasbrouck, Washington; *Vice-President,* Dr. Warren E. Page, Phoenix; *Secretary,* Dr. Benjamin F. Tefft, Jr., Anthony; *Treasurer,* Dr. Frank B. Smith, Washington.

Edgefield County (S. C.) Medical Society: Annual meeting at Edgefield on December 14. Officers elected: *President,* Dr. W. D. Ouztes; *Vice-President,* Dr. G. P. Corn; *Secretary-Treasurer,* Dr. J. G. Edwards.

Pickens County (S. C.) Medical Society: Annual meeting at Easley on December 4. Officers elected: *President,* Dr. C. N. Wyatt; *Secretary-Treasurer,* Dr. R. J. Gilliland.

Sumter County (S. C.) Medical Society: Annual meeting at Sumter on December 5. Officers elected: *President,* Dr. C. J. Lemmon, Sumter; *Vice-President,* Dr. M. L. Parler, Wedgefield; *Secretary-Treasurer,* Dr. E. R. Wilson.

Mitchell District (S. D.) Medical Society: Annual meeting at Mitchell. Officers elected: *President,* Dr. F. W. Freyberg, Mitchell; *Vice-President,* Dr. G. A. Clauser, Bridgewater; *Secretary,* Dr. C. S. Bobb, Mitchell; *Treasurer,* Dr. F. S. Kidd, Woonsocket.

Norwalk (Conn.) Medical Association: Annual meeting on December 17. Officers elected: *President,* Dr. W. B. Burnell; *Vice-President,* Dr. S. H. Huntington; *Secretary-Treasurer,* Dr. W. H. Stone.

Newton-Neshoba-Winston (Miss.) Medical Society: Annual meeting on December 16 at Newton. Officers elected: *President,* Dr. L. W. Cooper, Newton; *Vice-Presidents,* Dr. W. J. Chapman, Newton, and Dr. D. J. Rush, Philadelphia; *Secretary-Treasurer,* Dr. S. A. Majure, Dixon.

Waldo County (Me.) Medical Society: Annual meeting at Belfast on December 16. Officers elected: *President,* Dr. Elmer Small, Belfast; *Vice-President,* Dr. N. R. Cook, Brooks; *Secretary,* Dr. Adelbert Millett, Searsmont; *Treasurer,* Dr. O. S. Vickery.

Hancock County (Me.) Medical Society: Annual meeting at Bar Harbor on December 18. Officers elected: *President,* Dr. Frank R. Ober, Northeast Harbor; *Secretary-Treasurer,* Dr. George A. Neal, Southwest Harbor.

**Obituary Notes.**—Dr. William Henry Watson of Utica, N. Y., a graduate of the Hahnemann

Medical College and Hospital of Philadelphia in 1884, one of the founders of the New York State Homeopathic Hospital for the Insane at Middletown, and a member of its first board of trustees, surgeon-general of New York in 1880, and a regent of the University of the State of New York from 1881 to 1904, died at his home, on January 1, aged 83 years.

Dr. William Blaney Stevenson of California, Pa., a graduate of the University of Pittsburgh, Medical Department, in 1911, died at his home from diphtheria contracted during an epidemic of the disease in Daisytown, Pa., on December 19, aged 25 years.

Dr. William Stewart Reoch of Phenix, R. I., a graduate of the college of Physicians and Surgeons, New York, in 1896, and a member of the Rhode Island State and Kent County Medical Societies and a former president and secretary of the latter, died at his home from Bright's disease, on December 15, aged 43 years.

Dr. Frederic S. Sellew of New York, a graduate of the College of Physicians and Surgeons, New York, in 1881, and a member of the New York State and County Medical Societies, the Academy of Medicine, the New York Pathological Society, the Society of Medical Jurisprudence, the Lenox Medical and Surgical Society, and the Grolier Club, died at his home on December 28, aged 54 years.

Dr. Joseph Solatinow of Passaic, N. J., a graduate of the Eclectic Medical College of the City of New York, died at his home on December 26 after a short illness, aged 65 years.

Dr. Guy C. Marsh of Galion, Ohio, a graduate of the Cleveland University of Medicine and Surgery in 1889, died at his home, on December 26, aged 48 years.

Dr. Charles Kennedy of Troy, Ga., a graduate of the Baltimore Medical College, Maryland, in 1897, was instantly killed on December 26, when the carriage in which he was driving was struck by a railroad train. Dr. Kennedy was 38 years of age.

Dr. Henry F. Pahf of Brenham, Tex., retired, a graduate of the Hahnemann Medical College and Hospital of Philadelphia in 1868, died at his home on December 30, aged 74 years.

Dr. Ezra M. Rogers of Hartford, Wis., a graduate of the New York University Medical College in 1860, died at his home, on December 18, aged 81 years.

Dr. John L. Dryden, professor of anatomy in the College of Physicians and Surgeons of St. Louis, Mo., a graduate of the Homeopathic Medical College of St. Louis in 1891, died at his home after a long illness, on December 25, aged 49 years.

Dr. Melville Hutchinson Criswell of Cassopolis, Mich., a graduate of the Hahnemann Medical College and Hospital of Chicago in 1891, died at his home, on December 14, aged 50 years.

Dr. George Louis Farrell of Malden, Mass., a graduate of the Jefferson Medical College, Philadelphia, in 1895, a member of the Massachusetts State and Middlesex County Medical Societies, and Mayor of Malden for two successive terms, died at his home, on January 1, aged 45 years.

Dr. Paul R. Tainter of Callao, Mo., a graduate of the Hospital College of Medicine, Louisville, Ky., in 1902, and a member of the American Medical Association and the Missouri State and Macon County Medical Societies, was instantly killed in an automobile accident on December 27, at the age of 34 years.

## INFLATION OF STATISTICS AS EMPHASIZED BY A RECENT REPORT ON PRIMARY SPLENOMEGALY.

To the Editor of the Medical Record:

Sir:—Permit me to call attention to the unreliability of medical statistics in the determination of the prevalence of certain rare affections. As is well known, patients afflicted with rare, especially chronic, incurable diseases, loath to accept the death-sentence without appeal, usually make their rounds from one doctor to the other and from one clinic to another. Quite naturally every progressive physician takes special interest in such cases, and, as occasion arises, reports them in the medical press. It thus happens that the same case is manifoldly recorded by several physicians and the statistics often swell *ad infinitum*. This, in a way, is unavoidable. But it certainly is to be regretted when this duplication occurs with full knowledge of the succeeding writers. On November 4, 1911, I recorded in your very valuable journal two cases of "Primary Splenomegaly in Brother and Sister." In January, 1912, one of these cases was reported again by Dr. M. S. Reuben in the *American Journal of the Diseases of Children*. Though fully aware of my report, he failed to mention the fact. Now, one year later, in the December, 1912, issue of the *Journal of Experimental Medicine*, Dr. F. S. Mandlebaum has again reported the same case, without giving me credit for it, although, judging from a communication received from him in June of last year, he was familiar with my article in the Medical Record. Far be it from me to underestimate the great value of both of the highly scientific contributions to the study of the disease, but, because of its extreme rarity, this repetition of reports of its occurrence will only tend to minimize its importance and thus decrease the scientific interest in this still obscure affection.

Herman B. Sheffield, M.D.

New York.

## OUR BERLIN LETTER.

(From Our Regular Correspondent.)

THE GERMAN SOCIETY OF NATURALISTS AND PHYSICIANS—NON-OPERATIVE TREATMENT OF TUMORS—TOXINOTHERAPY, IMMUNOTHERAPY, AND CHEMOTHERAPY—RADIOTHERAPY IN CANCER—SECTION ON PSYCHIATRY AND NEUROLOGY—PENAL PSYCHOLOGY—SECTION ON HYGIENE—TUBERCULIN THERAPY—MODERN MILITARY SURGERY—DIFFICULTIES OF NAVAL SURGERY—BIOLOGY AND ITS PLACE IN THE EDUCATIONAL CURRICULUM.

Berlin, November 30, 1912.

The eighty-fourth annual meeting of the German Society of Naturalists and Physicians was held in the middle of September, 1912, in the city of Münster, Westphalia. The non-operative treatment of tumors was discussed by Czerny of Heidelberg. It may now be regarded as established that the combined method of treatment, namely, the use of surgical and other methods, can bring about the cure of cases of cancer that have hitherto been regarded as incurable. The future will decide whether or not this cure is a real one. It is to be regretted that society which contributes so many millions for the campaign against tuberculosis and other infectious diseases does so little to aid the cause whose ob-

ject is the eradication of cancer. The speaker discussed toxinotherapy, immunotherapy, and the recently lauded chemotherapy. In the last it is not possible to apply to human beings the results of animal experiments, for the toxic doses border too closely on the therapeutic ones. In the cancer hospital under the direction of the speaker certain promising researches were carried out by R. Werner, who used the slightly toxic but nevertheless active cholin salts. Following the favorable results on animals, the remedy was also tried on human beings, but not sufficient time has elapsed to enable one to draw any definite conclusion as to the therapeutic value of the cholin salts. Radiotherapy properly applied is of undoubted value. For further investigation there are demanded new cancer research institutes like that at Heidelberg. The speaker concluded that if such highly civilized nations as England and Germany would decide to build one dreadnought less, and with the $10,000,000 thus saved would build forty cancer research institutes, the conquest of cancer would not be so far off.

In the Section on Psychiatry and Neurology H. Többe of Münster delivered an address on the psychology of delinquents sentenced to life imprisonment. He reported on seventy murderers who at the time of the commission of the crime were quite healthy. In 40 per cent. of these individuals there were detected certain mental diseases. Prior to the commission of the crime 51.1 per cent. had been eligible for military service. Only a small proportion belonged to the class of habitual delinquents who followed crime as a trade. First offenders constituted 4.5 per cent. of the entire number; those who had already been convicted of a minor offence comprised 10 per cent.; while 40 per cent. included those who had served imprisonment for some major crime. The misdemeanors of those belonging to the first two groups were associated with marked symptoms of mental impairment. It may be regarded as proved that those criminals in whom homicide was the first crime, are to be differentiated from the habitual delinquents, and after release from prison become useful members of society. By far the larger percentage of those sentenced to life imprisonment become insane in prison.

In the Section on Hygiene, Tropical Hygiene, and Bacteriology, B. Möller of the Robert Koch Institute of Berlin discussed the present status of tuberculin therapy. The best results of this method are obtained when it is combined with the hygienic and dietetic measures of the sanatorium. Only in selected cases of incipient tuberculosis is the ambulatory treatment with tuberculin to be recommended. The use of tuberculin in slowly increasing doses is the best method of using it, which method avoids the production of reactions. Every case is to be treated on its own merits, according to its susceptibility to tuberculin. Observations extending over a number of years can alone guarantee success. The subcutaneous is the best route for the administration of tuberculin.

In the second general session Kuttner of Breslau read a paper on modern military surgery. A wider knowledge and the practice of asepsis have within a few years revolutionized military surgery. Modern arms produce less dangerous wounds than the older weapons. The main principle of modern military surgery is its conservative nature. The use of the probe is avoided on the field and the less urgent operations are postponed. The primary care of the wounded is provided for by the bandage packet with which every soldier is supplied, this being sewed on the lining of his coat. Aimless probing for bullets, unnecessary examination, and superfluous bandaging do most harm to the injured. The non-infected bullet is a harmless foreign body. Amputations necessitated by fractures resulting from infantry projectiles have become extraordinarily rare. In the case of all gunshot wounds of bones and joints the most important measure is immobilization by means of a bandage. Only the most urgent menace to life justifies an immediate operation. Much more unfavorable are the conditions with reference to abdominal injuries. On the battlefield operative procedures in these cases are practically impossible. Most difficult is the work of naval surgeons, as has been amply demonstrated in the war between Japan and Russia. It is characteristic of marine warfare that the entire surgical staff of a battleship may be wiped out, while the remaining personnel of the ship may survive. Such a happening is inconceivable in land warfare. In the battle on the Yalu a shell which fell upon the dressing station of the Japanese war vessel killed both surgeons and the greater part of the medical corps. Another peculiarity of naval surgery consists in the larger number of severe injuries and in the complicated nature of these injuries.

In the general session of the main sections on the natural sciences, the address by H. Czerny of Strassburg deserves special mention. He spoke of the necessity of instruction in biology in the higher schools and emphasized the importance of physicians acquiring a wider knowledge of biology than has been the practice in the past. Even early in their school career the pupils should be taught how to observe carefully natural objects. The entire race would benefit by a wider diffusion of instruction in biological science. It is to the want of this instruction that must be attributed the fact that in many cities there are built magnificent museums, court houses, and theaters, even before any thought is given to the introduction of an adequate water supply, an efficient system of sewers, or the erection of suitable hospitals. The dissemination of biological knowledge would ensure greater cooperation between the public and the medical profession. The significance of the purity and cleanliness of food products and of their proper preservation and preparation would be recognized by a properly instructed people, and many cases of disease would thereby be prevented. R. v. Wettstein of Vienna read a paper on Biology in its Relation to Modern Culture, and R. v. Hannstein of Berlin discussed the subject of Biology and the School.

---

## NINTH ANNUAL MEETING OF THE PHILIPPINE ISLANDS MEDICAL ASSOCIATION.

(From Our Regular Correspondent.)

MANILA, P. I., Nov. 19, 1912.

THE fifth session of the Philippine Islands' Medical Association took place at 10 A.M., November 7. The first paper read was entitled "Congenital Anomalies Encountered in a Series of Three Hundred Necropsies in Manila," by Dr. Jose Hilario. In this the author gave a tabulated list of the congenital anomalies found at autopsy.

The second paper was entitled "Experiences in Anesthesia at the Philippine General Hospital," by Miss E. J. Ochsner. In this paper the author stated that in accordance with the teachings in the

United States, ether could not be used satisfactorily in a tropical climate, like that of Manila, and that chloroform must largely be depended on. She stated that this, however, had not been her experience; ether had been successfully used, but the quantity was somewhat in excess of that which was required in a cooler climate. The ordinary drop method, without special apparatus, was found to be thoroughly satisfactory. She drew attention to the great difficulty in securing a satisfactory ether in the Philippines, and exhibited cans from well-known makers, which showed the poor condition in which the ether arrived here. On account of the fact that a large percentage of ether, in many of the cans, had evaporated, the residue did not have the anesthetic properties of the unchanged ether, and this residue, she believed, to be an injurious substance to use.

In the discussion which followed, Dr. Heiser stated that the question of unsatisfactory ether containers was an old one in the Philippines, and one that had received much attention in the past. Because of the fire risk, the steamship companies refused to carry the ether in the holds, consequently it was piled on deck, became wet, and the cans rusted and through the rust holes the ether escaped. Another difficulty was the greater heat of the tropics, and the long period which necessarily elapsed from the time that the ether was manufactured until it reached a Philippine hospital. By reason of the heat more gases were liberated and therefore the internal pressure was greater, and many small blisters in the solder that probably would not have opened in a temperate climate, are forced open here owing to the increased pressure. Some success had been had by lacquering the cans to prevent their rusting, but the difficulty of the blisters in the solder had not yet been overcome. Experiments were made in shipping ether in glass containers, but considerable difficulty was experienced on this account because if a glass container happened to crack or break the entire contents were immediately liberated, thus increasing the fire risk, whereas, if a tin can was broken, only a small quantity of ether would be liberated at a time and consequently the fire risk was reduced. Another difficulty with the glass container was that insect borers, like white ants, often destroyed the corks and permitted the ether to escape in that way, so that unless a glass stopper was used there might be loss caused in this way. Lately success had been had by importing ether in glass stoppered bottles packed in zinc-lined boxes, so that if any of the glass bottles were broken, the ether was at least not liberated so as to endanger other cargo.

The next number on the program was a brief demonstration by Dr. Ottofy, in which he illustrated by photographs and descriptions, artificial ears, noses, jaws, etc., which he had made for cases in which they were absent or had to be removed on account of surgical reasons. This completed the professional part of the program, and this session was immediately followed by the regular business meeting.

Among other business transacted, the following resolution was passed: "The Philippine Islands' Medical Association hereby strongly recommends to the Philippine Legislature the passage of such legislation as will bring about, at an early date, the use of unpolished, or undermilled, rice among those among whom rice is a staple article of diet."

The following officers were elected: *President,* Dr. N. J. Blackwood, of the United States Navy; *First Vice-President,* Dr. A. M. Saleeby; *Second Vice-President,* Dr. A. G. Sison; *Counsellor* for five years, Dr. R. E. L. Newberne; *Delegate to the American Medical Association,* Dr. R. P. Strong.

On Thursday, at 8 P.M., on the roof of the Manila Hotel, the ninth annual meeting was brought to a close by a social evening, at which the wives and friends of the members were present. Hon. Dean C. Worcester, Secretary of the Interior for the Philippine Islands, showed a series of moving pictures taken among the wild tribes.

Dr. Thomas Jackson, formerly of the Medical Reserve Corps, of the United States Army, and author of a textbook on tropical medicine, has accepted a position as medical inspector with the Bureau of Health.

Dr. Vicente de Jesus, the representative of the Philippine Government at the International Congress on Tuberculosis at Rome and at the International Congress on Hygiene and Demography at Washington has returned to Manila.

# Progress of Medical Science.

## New York Medical Journal.

*December* 28, 1912.

1. Salvarsan *versus* Mercury. E. W. Ruggles.
2. Municipal Supervision of Maternity. S. W. Newmayer.
3. Women in the Medical World. J. J. Walsh.
4. Progressive Deafness. J. A. Stucky.
5. Adequate Hospital Control. B. H. Waters.
6. Confidential Communications between Patient and Physician. L. M. Gompertz.
7. A Ruptured Ectopic Gestation Sac. F. W. Brandner.
8. A New Operating Urethroscope. G. Greenberg.

1. **Salvarsan versus Mercury.**—E. W. Ruggles believes that salvarsan is a very efficient ally in the symptomatic treatment of syphilis. Many lesions which have proved obstinate to or absolutely uninfluenced by the best forms of mercurial, iodide, and local treatment, have yielded almost magically to its action, and many patients with malignant syphilis who seemed doomed to an early death or deplorable deformity have been saved. Indeed its most remarkable results are attained in cases which have proved resistant to the action of mercury. Another great advantage is that one is often able to accomplish by a single treatment as much or more than by a prolonged course of mercury.

4. **Progressive Deafness.**—J. A. Stucky states that in non-exudative otitis media there is a history of variable degrees of deafness fluctuating in character. The so-called *paracusis willisiana* exists with the usual anomalies of hearing for voice and musical tones. The tinnitus and slight vertigo are aggravated by anything that accelerates the circulation or vasomotor disturbance in the labyrinth from psychic causes. The objective symptoms reveal nothing of a definite nature in the drum membrane by which one can determine the degree of deafness, this membrane appearing slightly changed or abnormal, as indicated by retraction or atrophy, opacity, or the presence of calcareous deposits. The condition of the Eustachian tube reveals no abnormality or pathological condition that can account for the impaired hearing; with both the subjective and objective symptoms indicating that the pathological changes which have so impaired the hearing function, have occurred slowly with increasing deafness and tinnitus. The bone conduction by the Webber test is increased, except in elderly people and in these we frequently find it diminished. Cases like these give a history of originating imperceptibly, and being progressive in nature, with usually no improvement after successive inflations, one concludes that, in addition to the exudative condition in the middle ear cavity, there has probably resulted ankylosis of the ossicular joints and

the fenestral structures. Cases like these, perhaps, prove more than any other ear trouble the correctness of the assertion that these diseases are a local manifestation of a systemic condition. Otosclerosis is the most embarrassing and most hopeless of all diseases of the ear of a non-infective nature. The etiology is still obscure, but the most important causes are syphilis, gout, arteriosclerosis, uric acid diathesis, pelvic diseases, and the influence of pregnancy. The subjective symptoms differ very little from those due to non-exudative otitis media, except in intensity. Giddiness or vertigo occurs less frequently, and seldom in aggravated form. The objective symptoms show practically no deviation from the normal drum membrane unless complicated by nonexudative otitis media. Tests by tuning forks give the Bezold symptom complex of (a) increased bone conduction, (b) negative Rinne, (c) elevation for lower tone limit. The majority of cases of these diseases give evidence of disturbance and faulty metabolism indicated by the presence of indican or excess of phosphates and urates in the urine, or there are present indications of previous attacks of rheumatism. By far the larger number present these indications. The next systemic condition most frequently observed is increased blood pressure or arteriosclerosis.

5. **Hospital Control of Tuberculosis.**—B. H. Waters states that the adequate hospital control of advanced or "open" stages of pulmonary tuberculosis cannot be attained without sufficient hospital accommodation and the enactment, if necessary, of special legislation conferring upon State and municipal health officers authority for compulsory removal and detention. This authority should be exercised whenever there is refusal to comply with sanitary regulations, when unsanitary home conditions exist, when the patient is of vicious character and habits, when others, especially children, are exposed to infection, and when the patient or the family are public charges or dependent upon charitable aid.

10. An Adenoid Curet. G. Sluder.

1. **Diagnostic Pitfalls.**—By R. C. Cabot. (See MEDICAL RECORD, Vol. 82, page 361.)

2. **Double Ureters.**—H. R. Stevens notes that if one will except the rare true cases of solitary kidney, when a blind ureter may be found on the other side extending up a short distance from the bladder, the inference is certain that for every ureteral orifice in the bladder there is a renal pelvis—perhaps more than one—and that these pelves do not communicate. Also there may be present ureters terminating at their distal ends blindly or in some part of the genital or urinary tracts other than the bladder. When a ureter crosses the median line to reach its associated kidney, that kidney is usually caudal to the one normally belonging on that side. Of two ureters running from one kidney to the bladder, that with the more mesial and more caudal opening almost always corresponds to the upper pelvis of the kidney. The history and general examination will offer valuable leads, but our surest means of diagnosing renal conditions accurately are careful comparative examinations of urines obtained by ureteral catheter, associated kidney function tests, and intelligent use of the *x*-ray. In baffling cases urine from different levels of the ureter should be collected and it is best to inject the silver solution through a large catheter first in the renal pelvis, then at successively lower points in the ureter, before radiographs are made.

3. **An Overlooked Function of Bartholin's and Cowper's Glands.**—D. T. Smith states that when the urine is voided the mucous membrane is in large measure swept bare of its free mucus, and this deprivation Nature sets out early to remedy. A contraction of the walls of these glands takes place, extruding mucus into the passages to take the place of that which has been washed away by the passing urine, thus protecting the denuded mucous membrane. The contraction of the gland walls is reinforced in the male by that of the walls of the urethra, and in the female by the contraction of the muscles about the outlet of the vagina. It is probable, too, that in all cases a reflex stimulus is conveyed to the glands which causes an increase in the quantity of their secretion. This condition is often a matter of distinct importance. In a large percentage of males the secretion is poured out with sufficient copiousness to cause it to be discharged from the urethra as a stringy mass; and many of these men consult their physicians about an imaginary spermatorrhea.

5. **Caloric Requirements of Bottle-Fed Infants.**—By R. H. Dennett. (See MEDICAL RECORD, Vol. 81, page 1161.)

6. **Moving-Picture Illustrations in Medicine.**—T. H. Weisenburg believes that the greatest value of moving pictures is to record diseases so that future generations of medical men may have a permanent record. In the future one will be able to exchange films of the different types of the same disease occurring in different countries. Rare cases may be permanently recorded. In the nervous wards of the Philadelphia Hospital a patient presented the clinical symptoms of inability to laugh on one side of the face, and yet was able to use the facial muscles for every other purpose. This patient died and his brain was obtained and carefully studied. This was the first occasion in medicine when it was possible to give a history of the case, show the specimen, and at the same time illustrate by motion pictures what the patient suffered from during life. These pictures are of the greatest scientific value because they furnish a new means of detection. The author has, for example, a photograph of a man with Jacksonian convulsions in which the fit starts in the right corner of the mouth and takes in successively the right side of the face, eyes and eyelids and then the muscles of the right hand and then the whole right arm. Ordinarily a convulsion of this type is so rapid that there is little opportunity to make extensive observations. In the demonstration of these pictures on the screen the size of the subject is greatly enlarged and it is most interesting to watch the succession of muscular twitching and to show the movement of both eyes, eyelids and brow.

7. The Vaccine Treatment of Hay Fever. A. G. H. Lovell.
8. Abnormal Tuft of Hair and Plica Neuropathica. W. K. Sibley.

1. **Pharmacotherapy of Pneumococcus Infections.**—Sir Almroth E. Wright, W. P. Morgan, L. Colebrook, and R. W. Dodgson have found that ethylhydrocuprein hydro-

chlorate does not come up to the ideal of being poisonous for the pneumococcus, and non-poisonous for the nobler tissues of the patient. The drug is in the human organism —and this holds true also in some measure of its congener, quinine—*optico-neurotropic*. In the experience of A. Fraenkel three cases of amblyopia—all of which recovered —occurred among 21 pneumonic cases treated with the drug. The dose here appears to have ranged between 1 and 2 grams daily. In the meantime, in the authors' experience in Johannesburg, two cases, one of which went on to amaurosis, occurred in eight pneumonic patients treated. The doses of ethylhydrocupreinhydrochlorate ranged here between 0.5 and 2 grams daily. They were administered in some cases by the mouth, in others subcutaneously, and in others, again, both by the mouth and subcutaneously. In a third series of nine pneumonic cases which were treated by J. Parkinson at the London Hospital there were three cases in which the pupils became very widely dilated under the influence of the drug. The doses of ethylhydrocupreinhydrochlorate here ranged between 0.5 gram or less to 1.5 grams daily.

2. **Chronic Intestinal Stasis.**—W. Arbuthnot Lane employs the term "chronic intestinal stasis" to indicate such an abnormal delay in the passage of the intestinal contents through a portion or portions of the gastrointestinal tract as results in the absorption into the circulation of a greater quantity of toxic or poisonous materials than can be treated effectually by the organs whose function it is to convert them into products as inoccuous as possible to the tissues of the body. When these poisons and their products of conversion exist in excess in the circulation they produce degenerative changes in every tissue and in every organ in the body. It is probable that the textures of those organs whose business it is to convert, carry, and eliminate them suffer more than do the other tissues of the body which are merely permeated by them. In proportion as the stasis is prolonged, so under the influence of a progressive strain greater than they are able to bear these several organs undergo a degeneration which proceeds with increasing rapidity as the condition advances. The liver is the most important converter of the poisons, and the kidneys and skin are the chief excretors of the products of conversion. Unless the capacity of the several tissues of the body to resist the entry of certain organisms is inhibited by the autointoxication resulting from intestinal stasis it is impossible for these diseases to develop. The author refers more particularly to tuberculosis, rheumatoid arthritis, and similar diseases. Therefore, to meet these diseases he adopts means to improve the drainage scheme, whether simply mechanical or operative, with the most excellent results. This is nowhere better exemplified than in the extraordinarily rapid disappearance of large tuberculous glandular masses in the abdomen after disconnection of the big bowel. Pigmentation of the skin is a very marked feature in advanced cases of stasis, especially in patients with dark hair. Following almost immediately upon exclusion of the large bowel, the cold, blue, clammy hand is replaced by a warm, pinkish, dry one. Cancer of the breast, of the ducts of the liver, or of the pancreas is, according to the author, the result of chronic intestinal stasis.

5. **Chronic Appendicitis and the Stomach.**—C. Singer concludes that chronic appendicitis has been frequently found in association with gastric symptoms. When this association occurs, a gastric or duodenal ulcer may or may not be present, but in all cases the gastric juice has yielded abnormal analytical results. The abnormalities may consist of hypersecretion or of hyposecretion both of chloride and pepsin, of the presence of a peptolytic ferment, and of the elevation of the "nitrogen factor." These abnormalities can best be explained as due to toxic substances which act both on the stomach and on the appendix. Removal of the appendix does not always relieve or improve the symptoms.

6. **Early Signs of Mediastinal Tumors.**—L. Roberts emphasizes (1) the importance of obstruction of the azygos veins in explaining symptoms and localizing obstructions; (2) the importance of paying full attention to the *quantity*, as well as the *quality*, of the air entry; (3) the importance of estimating properly the significance of referred pains, especially of shoulder pain, which, though rheumatic in type, persist in spite of treatment; and (4) the seriousness of idiopathic pericardial friction in elderly people.

1. Some Manifestations of a Healthy Heart in the Young Frequently Taken as Indications for Treatment. J. Mackenzie.
2. Observations Upon the Acoustic Phenomena in Mitral Stenosis. T. Lewis.
3. Regional Anesthesia. F. Rood.
4. Case of Stokes-Adams Disease. J. L. Falconer.
5. Nervous and Mental Symptoms in a Case of Addison's Disease. J. G. P. Phillips.
6. High-Frequency Currents in Trigeminal Neuralgia. W. F. Somerville.

1. **Manifestations of the Healthy Heart in the Young.** —By J. Mackenzie. (See page 81.)

3. **Regional Anesthesia.**—F. Rood summarizes the characteristics of this form of anesthesia as follows: (1) Granted that a suitable anesthetic solution is introduced around the trunk of a nerve, the whole area supplied by that nerve becomes anesthetic—bone, muscle, fascia, skin, etc. (2) The method can be used for operations upon inflamed tissues provided that the injection around the nerve trunk be made at some point well above the septic area. (3) The anatomical relations of the part to be operated upon are not obscured by edema caused by a large quantity of injected fluid, as is sometimes the case with wide infiltration method. (4) The anesthesia lasts for several hours. (5) The anesthetic area is clearly defined by the anatomical distribution of the nerves. Consequently there is no risk of suddenly overstepping the limits of the anesthesia, with most unpleasant results to the patient. A very important factor in the success or otherwise of this form of anesthesia is the solution used. Either eucaine, stovaine, or novocaine may be employed, but the best results have been obtained with novocaine. A 2½ per cent. solution of novocaine in distilled water is prepared and sufficient sodium chloride added to make the fluid isotonic with the blood. The whole is then sterilized by boiling, which can be done without detriment to the novocaine.

4. **Stokes-Adams Disease.**—J. L. Falconer reports a case of this condition occurring in a woman 70 years old. The points of interest are the occurrence of the disease in a woman and the combination of all types of attack, namely, syncopal, epileptiform, and apoplectiform, in the one patient.

6. **High-Frequency Currents in Trigeminal Neuralgia.** —F. Somerville reports the case of a woman aged 60 years who suffered from severe trigeminal neuralgia of eight years' duration. The attacks were frequent and even in the intervals between them the patient lived under the constant fear of their return. She had been at one of the English spas, and had been treated by ionization, but without benefit. The author began high-frequency treatment November 2, 1911, and continued this method of treatment daily with one or two intermissions until June, 1912. By that time the attacks of neuralgia had completely disappeared, and the patient's appearance and general sense of well-being showed a corresponding measure of improvement.

*December* 16, 1912.

**New Leg Phenomenon.**—Piotrowski refers to the successive establishment of the reflexes which are known by

the names of Westphal, Babinski, and von Bechterew. By means of such resources we are now able to diagnosticate many serious nervous diseases in their earliest stages. The author's new contribution is as follows: If one percusses the tibialis anticus muscle while the leg is relaxed by pronation or suspension at a point close to its origin, say between the tuberosity of the tibia and head of the fibula, or two fingers' breadth below this point, one sees in many cases a reflex dorsal flexion and supination of the foot. This reaction corresponds to the motor effect of the physiological function. The technique is the same as that used in testing the patellar reflex. The attention of the patient should be diverted the while by Jendrassik's maneuver or some other resource. The author names the phenomenon the anticus reflex. In health it is not constant and if present not pronounced. In nervous and neuropathic subjects it is quite distinct and unequivocal. It should occur in all cases in which there is a natural tendency to quieting of the reflexes without the presence of actual disease, and which implies usually a slowing of cerebral inhibition—old, lean subjects, bed ridden and marantic subjects. Naturally its chief significance must occur when greatly exaggerated or absent, or asymmetric, other things being equal. If it occur symmetrically in a subject with slight exaggeration of other reflexes in a patient in apparent health it simply indicates a neurotic disposition. When it is pathological in significance some of the other reflexes will be in evidence. Thus far the author has tested 115 patients with the most varied diseases and including a number of healthy controls. At present he sums up as follows: The anticus reflex is almost always accompanied by increased patellar reflex, but the latter is much more a physiological phenomenon, present in all healthy subjects. Its chief value is seen in connection with organic lesions of the central nervous system, especially when spastic, but its behavior here is not typical—there is simply an irregular manifestation of some sort as variability, asymmetry, exaggeration. In general in diseased states its paradoxical behavior suggests that something is wrong.

**Autovaccination of the Tongue.**—Lublinski has previously reported an accidental vaccination of the nasal mucosa. This was not an autoinoculation as the virus came from the pustules of a child and was carried into the mother's nose by a handkerchief. The second case was that of a young child who after five days of normal vaccination developed high fever with swelling of the tongue. On the eighth day after vaccination the temperature was still high, the cervical and nuchal lymphnodes greatly swollen, more to the left than right side, while chiefly upon the left half of the dorsum linguæ were seven plaques the size each of a lintel. They extended from tip to base of the tongue, the margins and under surface being free. Each efflorescence showed a red areola and a yellowish secretion. The child had scratched the pustules as they appeared on her arms and had then sucked her fingers. Such a course could be of common occurrence so that a predisposing cause must be evoked. This was readily apparent in the fact that the child was subject to fissures in the tongue. But even with this predisposition the unique character of the lesion is explicable with difficulty. The missing link is doubtless seen in the supposition that immunization of the organism had not occurred, so that three factors made up the causal nexus. The course of the lesion was favorable in the main, and the only persistent evidence of anything unusual was the enlargement of the lymphnodes. The child was of notably lymphatic habitus.

*December 10 and 17, 1912.*

**Harmfulness of Distilled Water.**—Oehler considers this subject in its relationship to the inferior animals. It has long been known that unicellular organisms, plant and animal, soon perish in it, that it deprives muscle tissue of its irritability, that it is hemolytic, etc., etc. In man it is an open question whether the consumption of distilled water works harm. Recently it has been learned that artificial ice, from which the saline matter has not been crystallized out, is well borne in disease; while saltpoor melted natural ice, snow water, and glacier water exert an unfavorable action on the mucosæ when swallowed freely. It must be asked, however, in what manner this saltfree water disagrees. Is it because it attracts saline matter from the tissues? To throw some light on this point the author fed mice with the sound of Marks' method, giving them 1 to 2 c.c. at a time. As a result most of the animals developed hemoglobinuria about half an hour after the feeding. There was albumin in the urine but no formed elements appeared. Within three hours the urine had again become normal. A second feeding on the next day appeared to show that the animals had acquired some immunity but the phenomenon must be explained otherwise. The hemoglobinuria supervenes in the same animals upon injection; five minutes after the water is thrown into a vein the urine is red. Hence no actual immunity has resulted. If a certain amount of saline matter is added to distilled water no hemoglobinuria results. The bearing of this line of experiment on mankind is as yet unknown. The vulnerable tissues would naturally be the gastric mucosa, blood, and kidneys.

**A Simple Resource for the Differentiation of Ascites from Flaccid Ovarian Cysts.**—Dienst states that cases sometimes occur in which this differentiation cannot be made by the customary tests, so that trial laparotomy alone remains. This may be refused and in such a case puncture gives relief from the pressure symptoms. A test of the punctate is inconclusive, and cases have even occurred in which chylous ascites has been confounded with certain cystomata. The author would puncture for diagnosis in all doubtful cases. Then as ascites fluid always contains fibrinogen, while the latter is never present in cysts, he adds a third of its volume of salt crystals to some fluid in a test tube. Upon standing fibrinogen, if present, appears as a precipitate.

**Typical Street Railway Injury.**—Frank has seen several cases of injury due to the brass arches which serve to divide the lengthwise seats into individual compartments for passengers. These are constructed of round smooth brass rods and their highest point above the seat level is about 30 cm. It happens at times that women as they are seating themselves accidentally sit upon these brass arms in such a manner that the genitals are injured. A jolt of the car is probably responsible for the mishap. In one victim the right labium majoris was bruised and swollen. Another sustained a severe immediate hemorrhage from a laceration between the clitoris and meatus. In these two cases no serious consequences resulted but a wound of the urethra could result disastrously. The offending structure is not present in cars of the latest construction.

**Simultaneous Occurrence of Achylia Gastrica and Achylia Pancreatica.**—Gross calls attention to the well-known fact that patients with hypo- or achlorhydria often first consult the practitioner for diarrhea. The stomach in these cases supplies no symptoms whatever. We may assume in these cases several injurious consequences to the intestine of absence of gastric juice—for example, defect of its antibacterial action on intestinal flora. But none of these explanations really explains, for in many instances of pure achlorhydria we do not see diarrhea. A much more plausible supposition for these diarrhea cases is that there is associated an achylia pancreatica, a matter which should not be difficult of verification. The author has for several years past been testing the pancreatic function in all cases of achylia gastrica with diarrhea, con-

trolled by similar investigation of cases without diarrhea. The author does not appear to have tested the pancreatic activity beyond examination of stools for their tryptic activity on casein. Nothing is said of tests for fat in the stools, and fatty diarrhea is not even mentioned beyond the statements that we are not dealing with organic disease of the pancreas, and that the condition is really a hypochylia of the pancreas which is chiefly manifested by tryptic insufficiency. The author treats these cases successfully with a combination of HCl and pepsin and pancreatin.

**Abstinence Delirium of Alcoholics.**—Fürer refers to the newer doctrines of alcoholism specialists that abstinence delirium is more or less a bugbear and that the use of the drug may commonly be suppressed at once without prejudice, supposing, of course, that the patient is to be under proper treatment. The public and rank and file of practitioners do not agree with the sanatorium men and in theory the contention of the latter seems all wrong. During the past fifteen years the author has treated 500 chronic alcoholics with sudden withdrawal of drink. The patients were naturally of the upper classes, as the poorer individuals cannot avail themselves of private sanatorium treatment. The ages varied from 16 to 64 and 46 were females. The type of alcoholism was that dependent upon a steady impulse to keep constantly intoxicated, either temporarily or the year around. The amount and kind of drink taken varied widely, the record being held by a man who drank daily a liter of 96 per cent. alcohol with added amounts of beer, wine, and the ordinary spirituous drinks which were taken in accordance with the requirements of thirst. The most conspicuous effect was temporary failure of mental power in connection with the demands of business and personal and social exactions. There was a state of over-anxiety or fear, which was expressed incidentally in connection with the abolition of the habit—a fear of disastrous consequences or intense suffering, or both. Moral dereliction was frequently in evidence, as were also alcoholic epilepsy, Korsakoff, and other forms of alienation and of course delirium tremens. Of somatic disturbances there were tremor, neuritis, and gastroenteric disturbances. On the other hand, myocarditis, arteriosclerosis, renal and hepatic diseases, and diabetes were not greatly in evidence. As one-half the men had contracted syphilis at some period the arteriosclerosis, hepatic cirrhosis, and some other lesions could be set down in part to this component. Upon this background the author studied the matter of abstinence delirium. The patients were at once placed on rational treatment in connection with suppression, and but seven cases of delirium tremens appeared—a very small number, but sufficient to prove that abstinence delirium really exists, and under unfavorable conditions might even be of common occurrence, thus bearing out the contention of the old-time practitioner and public.

## Deutsche medizinische Wochenschrift.

*December* 12, 1912.

**Trachoma-like Affection from Blastomycetes.**—Stiel calls attention to the fact that several Italian investigators claim to have found in trachoma cells which they regarded as blastomycetes. More recently Prowazek and Leber mention the find of yeast cells in a trachoma native to the South Sea Islands. The fungi had not been obtained in cultures, perhaps because of the conviction that a secretion from the conjunctiva is necessary for this purpose. The converse should be true for the discharge from a diseased eye must contain other microorganisms in addition to the one accused. The author has therefore chosen to use only solid trachomatous tissue for cultural purposes. Study of the subepithelial tissues by the author revealed bodies which as closely as possible resembled those described by the Italian investigators. But attempts to cultivate the supposed blastomycetes met with failure for the time being as has happened with all the predecessors. At last the author succeeded in obtaining a pure culture, which agreed with Busse's "pathogenic yeast." Attempts to inoculate the conjunctivæ of blind subjects—naturally with their full permission—ended negatively. In a case seen in the clinic in which diagnosis lay between trachoma, chronic gonorrhea, and tuberculosis, the author made exhaustive studies and could seemingly exclude all three of these affections. Some so-called trachoma bodies were present but not to a greater degree than are seen in miscellaneous affections of the eye. The important finds were yeast cells and staphylococci. The former the author regards as the cause of ordinary trachoma, and he has already named it "saccharomyces trachomatis." He feels sure that we shall soon succeed in inoculating this microorganism.

**Principles of Psychotherapy.**—Veraguth attempts to build up a rational system of psychotherapy from the pioneer work of various authorities. The psyche of an individual must depend upon the "conflict of development," which is naturally largely sexual in character. Another element is desire for truth. These tendencies are naturally suppressed. There is a continual conflict between the young and their elders. Only recently have attempts been made to study the soul of the child which must naturally correspond to a certain stage of racial development. The infantile conflict sometimes remains unsolved through physical development which may go ahead unchecked in all other respects. The author speaks of normal full development as biologic correcture. The latter comes about through a sort of vicarious action in which arrested development in one direction may be compensated in another. It is common experience that neuropaths are often lively children. Psychotherapy embodies two principles, first the making of the subject acquainted with the heights and depths of his own soul, and second, the application of artificial biological correcture.

**"Secondary" Tuberculosis.**—Bacmeister and Rueben have made extensive researches into the content of circulating blood in tubercle bacilli and have come to some startling conclusions. It is, of course, understood that the blood of consumptives is thus infected but that a bacillemia is also compatible with incipient and healed tuberculosis and in scrofulous affections means that our entire knowledge of tuberculosis is in need of revision. The authors have confirmed the finds of their predecessors in all these particulars, but announce that the same acid-fast bacteria circulate in the blood of nontuberculous men and animals, in which a von Pirquet reaction is negative. The claim must be upheld for the time that this bacillemia cannot represent a tuberculous infection as there is no corroboration of its pathogenicity. Animal experiment gives negative results. The chief importance of these discoveries is that the demonstration of these bacilli in the blood has no value without some evidence of pathogenicity. For the bacillemia the authors employ the designation "secondary" tuberculosis, although the purport of this adiective is not quite apparent.

---

**Auricular Fibrillation and Its Effects Upon the Circulation.**—T. Lewis states that when the auricles fibrillate, the following effects are observed: 1. The arterial blood pressure may rise, fall, or remain stationary. Usually it falls. If it falls, it generally rises again towards or to the initial pressure. 2. The venous pressure changes are the reverse of the arterial. 3. The intestinal volume and the cardiac output changes are in the same direction as those of arterial blood pressure. 4. From these observations it may be concluded that the peripheral circulatory effects are purely passive. 5. The volume of the heart decreases except in instances where there is reason to believe that the circulation is failing.—*Journal of Experimental Medicine.*

## Insurance Medicine.

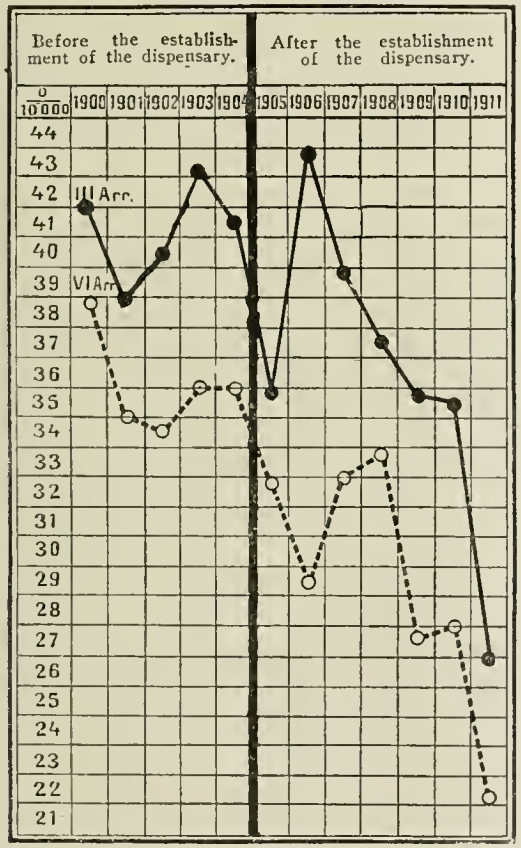
### REDUCTION OF THE MORTALITY FROM TUBERCULOSIS.

(From Our Insurance Correspondent.)

PARIS, December 23, 1912.

To lower the mortality of any disease is certainly of prime importance to all life insurance companies and where this can be done by preventive measures with judicious administration and care, the primary financial outlay is certainly small when compared with results such as those we are about to quote.

Dr. Jules Courmont of Lyons, France, in an interesting atricle in the *Presse Médicale,* shows the good work which has been accomplished in Lyons in the crusade against consumption by systematic preventive work on certain well-planned lines thoroughly carried out. The Antituberculosis Dispensary of Lyons was opened in 1905, and after seven years of work the results obtained are most satisfactory in every respect. The dispensary consists of a large well-aired and ventilated building with accommodation for bathing, laundry, and disinfection of clothes, consulting rooms, waiting rooms, and a laboratory for analyzing sputum. There are three attending physicians and each physician has a certain number of families allotted to his care so that he may follow the cases rationally.



Mortality from tuberculosis in the third and sixth wards in Lyons before and after the establishment of the dispensary.

Two inquiry agents are included in the staff, whose duty consists in visiting and inquiring after different families and educating the patients in the principles of hygiene. These men are present at the consultations and make sure that the patients go in in order with their cards and case-notes so that no time is lost. Two employees have charge of the disinfection of the houses in which tuberculous patients are living. The houses in such cases are disinfected once a month. One employee in the dispensary has care of the disinfection of the patients' linen and of the baths and douches for the patients.

Dr. Courmont then describes the arrangements made with the town authorities to insure the cooperation of the town with the dispensary for the providing of food to poor patients, and the supplying of separate beds to contagious patients in their homes. Special supervision is given to such patients and the other members of the family.

The statistics given are most useful and interesting and we shall quote them here. Since 1905 2,769 tuberculous families have come under the care of the dispensary, the following being the details:

| | |
|---|---|
| Total tuberculous cases | 766 |
| Contagious cases | 240 |
| Deaths from tuberculosis | 110 |
| Consultations | 9,037 |
| Visits by inquiry agents | 2,855 |
| Houses disinfected after death or departure | 218 |
| Houses disinfected during residence of infected patients | 1,255 |

From this some idea of the work done may be obtained. Tables of amount of linen washed, meat distributed, etc., are also given. If we now turn to the results obtained, Dr. Courmont explains how the mortality decrease is due to the work of the dispensary. Note must also be taken of the fact that the first mortality figures are too low as the notification of deaths from tuberculosis was frequently not a complete report, and this explains how the mortality appears in the reports of the first year to have suddenly increased, whereas this is merely due to more careful registration of deaths.

| | Inhabitants | Mortality | |
|---|---|---|---|
| Year. | Census of 1910. | Totals. | Per 10,000. |
| 1905 | 459,099 | 1,506 | 31.9 |
| 1906 | 472,114 | 1,726 | 36.5 |
| 1907 | " | 1,615 | 34.2 |
| 1908 | " | 1,544 | 32.7 |
| 1909 | " | 1,496 | 31.7 |
| 1910 | " | 1,462 | 31.1 |
| 1911 | 523,796 | 1,344 | 26.1 |

The mean tuberculosis mortality during the five years 1900-1904 was 35.4; during 1911 it was only 26.1. This shows a gain of 9.3 per 10,000 inhabitants or 483.6 inhabitants per annum in the town of Lyons.

In a chart which is here given it is shown that the mortality has fallen most notably in the poorer quarters of the town in the third ward from 42 to 27 per 10,000 and in the sixth ward from 39 to 22.

---

**Some Manifestations of a Healthy Heart in the Young.**—James Mackenzie has been impressed with the fact that a large number of young people are subjected to many forms of treatment because of the presence of certain phenomena which experience has taught him are signs neither of disease nor of impairment. Cardiac symptomatology has been involved in a state of confusion, not only with reference to the significance of irregular action of the heart, and of murmurs, but also with reference to prognosis. Practically every writer who gives the matter his serious attention is forced to admit that we do not possess the data on which to build a resonable and sound prognosis. One of the

greatest and most experienced clinicians, the late Sir William Gairdner, has accurately described the position of the medical examiner for life insurance in his method of estimating a life value. He says: "There is an incalculable element in most of the cases . . . which we deal with in the most curiously unsatisfactory way, either by rejecting the life altogether, or by putting on a big loading, which, it must be admitted, we assess upon no very sound or clear principles, or, on the other hand, by winking at the defect and passing it over." He points out that there are no reliable data on which to estimate the prognostic significance of murmurs and irregularities. This description of the absence of reliable data on which to base a prognosis holds good to-day, not only in life insurance, but wherever a prognosis is based on a physical examination.

Irregular heart action is a common manifestation, but one whose nature and significance are not clearly explained in textbooks. The great majority of heart irregularities can be divided into four groups, all differing in the mechanism of their production and in their clinical significance. These groups are the pulsus alternans, the irregularity of auricular fibrillation, the extrasystole, and the youthful type of irregularity. (1) The pulsus alternans is a form which is regular in its rhythm, but one in which a large beat alternates with a small one. The pulsus alternans occurs only when there is great exhaustion of the heart muscle. It may be that the exhaustion is only temporary, as in the tachycardias which arise from an abnormal action of the heart, or it may arise from exhaustion due to such profound alterations in the heart muscle that it indicates in many cases an exhaustion so extreme that death will shortly follow. (2) In auricular fibrillation the irregularity is of a very disorderly kind. From the point of view of the future life of the individual it has a varied significance. It occurs in 70 to 80 per cent. of all the cases of heart failure with dropsy. (3) The extrasystole is extremely common in adult life and rather infrequent in the young. It is due to a premature contraction followed by a long pause. The vast majority of people who show it are in good health and never suffer from heart failure. (4) The youthful type of irregularity is characterized by a variation in the length of the diastolic period. It may appear and disappear in the same individual for no perceptible reason. Every healthy individual probably shows it at one time or another. It is found most frequently and most markedly when the patient lies in bed after a febrile attack, but it is often found in boys and girls in perfect health. The author has watched those showing it grow up and pass into adult life and has never found a single case in which it has been associated with any form of heart failure.

Functional murmurs in the young in the absence of evidence of muscle affection are signs neither of disease nor of impairment. A murmur or an irregularity is of significance only when it is associated with some manifest impairment of the heart muscle. What are the evidences by which one can recognize affections of the heart muscle? These evidences are: (1) Increase in the size of the heart, due either to dilatation or to hypertrophy of its walls, particularly if associated with persistent increase in the rate of the heart and marked loss of power. (2) Murmurs are not necessarily a sign of dilatation. (3) The condition of the functional efficiency of the heart. This is the best and most accurate, and, in fact, the only reliable method of estimating the condition of the heart muscle. This method consists in finding out how the heart responds to effort and recognizing the symptoms which indicate its exhaustion. The chief symptoms are subjective.

The method of estimating the heart's strength by testing the functional efficiency, which is the most essential part in every examination, has been to a great extent neglected. In proof of this one need only consider the insurance certificate which medical men fill out. All the questions are restricted to the physical examination and not one is directed to finding out the functional efficiency of the organ, by which only the facts which are essential to a prognosis of the heart's condition can be ascertained. Notwithstanding this fact, the books which are supposed to guide the medical examiner give no hint that such a method exists. The result is that individuals are accepted at normal rates because a physical examination revealed no abnormality, whereas if an inquiry had been directed to the functional efficiency of the heart, the symptoms of exhaustion which heralded the unexpected death of the individual would have been revealed. On the other hand individuals are rejected for life insurance because of the presence of some harmless manifestations, whose significance the examiner does not understand, and whose value he can not appreciate, simply because he fails to apply and to appreciate this method of testing the heart's efficiency.—*British Medical Journal,* December 21, 1912.

**Softening of the Brain Acknowledged as the Result of Accident.**—Räuber relates the case of a man who sustained a fall of 4 meters height upon the nates, which, as a consequence, showed bruises. The victim was much frightened, and unable to recall whether he had lost consciousness at all. He lay in bed a fortnight and did not recover wholly from the effects of the injury for six months. No physician had been consulted at any time. Three years later, he was pronounced of unsound mind (circular insanity) but this was not attributed to the accident. When the author first saw the case, the subject presented the picture of dementia paralytica. The pupils were narrow and rigid, the tongue tremulous, no knee reflexes. The first signs had been noted as an alteration of disposition about six months after the injury. His health before the latter had been excellent. The author gave his expert opinion that the shock of the injury was calculated to precipitate first a tabes dorsalis and later the cerebral softening. Such cases have been reported with this expertisation. Goldscheider, in a deposition, stated that the existence of such a sequence was well recognized. The victim upon the author's testimony was awarded his accident insurance, but the case was at once appealed. A further expert opinion held that the case was one of taboparesis. Since the syphilitic foundation of the latter was recognized, a superposed trauma must answer two requirements. 1. It must be a considerable injury, but not necessarily involve the cranium directly. The shock to the body at large and especially the psychic shock must be taken into account. 2. A certain interval, from a few months to eighteen months, must have elapsed before the symptoms appear. Had it not been for the accident, the patient would doubtless have been able to earn his living for an indefinite period.—*Zeitschrift für Versicherungsmedizin,* 1912, V. Heft, 10.

# Book Reviews.

Wheeler's Handbook of Medicine. By William R. Jack, B.Sc., M.D., F.R.F.S.G., Assistant Physician to the Western Infirmary of Glasgow. Fourth Edition. Price $3, cloth; $3.25, flexible leather. New York. William Wood & Company, 1912.

The present edition of this well-known work contains a new section on Intoxications, and new articles on some of the Tropical Diseases. There is also a brief synopsis on Immunity. The other articles have been carefully revised, and some of them have been rewritten. An important feature of this book is the correlation of symptoms with the facts of anatomy and physiology; this makes it particularly useful to the student in connection with his work in the hospital and dispensary. The subject of treatment is not shirked, and the book can be recommended as one of the best of the small works on Practice.

Ueber Serodiagnostik und Serotherapie in der Augenheilkunde. Von Privatdozent Dr. Otto Kuffler, I. Assistant der Grossherzoglichen Universitats-Augenklinik in Giessen. Price 8 M. Halle A. S.: Carl Marhold Verlagsbuchhandlung, 1912.

Kuffler's brochure of 56 pages takes up the consideration of the subject of diagnosis and therapy in the diseases of the eye by means of sera and vaccines in a very thorough way, giving methods, technique, symptoms induced and results. The theories to explain reactions and effects are discussed. The author enters into a careful consideration of the relation of the various diseases of the eye to infection and, by weighing the evidence obtained by personal laboratory research and a study of the literature on the subject, arrives at conclusions that are of much clinical and therapeutic value. An extensive bibliography is attached. The monograph is worthy of careful perusal by all who practise ophthalmology.

Beiträge zur Chemotherapie der Tuberkulose. Nach den Vorträgen von Prof. Dr. Gräfin von Linden, Bonn; Prof. Dr. E. Meissen, Hohenhonnef; Dr. A. Strauss, Barmen. Price M. 1.50. Würzburg: Verlag von Curt Kabitzsch, 1912.

In this contribution Prof. Dr. Gräfin von Linden speaks of her successful experiments in treating tuberculous cattle with methyl-blue and copper salts. Professor Meissen, the director of the Hohenhonnef Sanatorium, speaks of his experiments with copper salts on 47 patients. While not over-enthusiastic, he thinks that chemotherapy has a future and encourages further investigations. What seems from the reviewer's point of view rather remarkable and perhaps favorable is the rather slow therapeutic effect of the copper salts on the active lesions. Strauss relates a case of lupus and one of a tuberculous abscess of the thigh successfully treated by local injections of jod-methyl-blue, 6 c.c. twice weekly, and internal administration of copper albuminates.

Contributions a l'Étude du Traitement des Tuberculoses Externes par les Injections Modificatrices. Les Injections d'Huile Gomenolee. By Dr. Jacques Tribes. Price 2 francs. Paris: A. Maloine, Editor.

This monograph of 82 pages gives a description of the author's method of using and the successful results obtained from the gomenol oil in localized tuberculosis of joints and glands. Gomenol is extracted from the young leaves of one of the varieties of *Melaleuca viridiflora*, a tree indigenous to New Caledonia. Its essential therapeutic qualities are ascribed to the turpentine, of which it contains to a very large amount.

Beiträge zur Klinik der Tuberkulose und Spezifischen Tuberkulose-Forschung. Vol. XXIII, No. 1. By Dr. Ludolph Brauer. Price M. 6.50. Würzburg: Curt Kabitzsch Verlag, 1912.

This is an unusually interesting number of the Beiträge, comprising mainly the researches conducted in the new sanatorium for the tuberculous at Schömberg, of which G. Schröder is the physician in chief. The latter, in collaboration with Drs. Kaufmann and Kögel, contributes a remarkable article on the rôle of the spleen as a defensive organ in tuberculous infections. In a subsequent article by Schröder himself, entitled "Tuberkulin-Behandlung," he comes to some very interesting conclusions which tuberculin enthusiasts may well take to heart. He says among other things that the use of tuberculin as a means of early diagnosis in lung tuberculosis is scarcely of any value, the possible usefulness scarcely compensating for its danger; that pathological and biological researches and animal experimentations do not prove that the non-reaction to tuberculin guarantees a sure cure, and that statistical data of institutions likewise confirm this conclusion. He states that those supposedly rendered immune by tuberculin are seemingly inclined to severe relapses, and that tuberculin susceptibility is a phenomenon of immunization that cannot be artificially removed. With the very smallest and not too frequently administered doses of tuberculin a cure may be helped along, but the principal therapeutic factors consist in the hygienic, dietetic, and physical methods. Lastly, he says that the use of tuberculin in general practice is for the time being still to be cautioned against.

Other interesting articles in the same number are one by Kögel on the von Pirquet reaction in graduated doses and its relation to prognosis in pulmonary tuberculosis. Kögel thinks it most probable that a strong reaction in early cases is a rather favorable prognostic sign. Kaufmann contributes two more articles, one of value in our studies of artificial pneumothorax. He watched the changes of the pleura and lung in a healthy dog in which he had produced artificial pneumothorax. In his conclusions he speaks of the relatively few cases in which artificial pneumothorax is indicated, but he admits that when it is indicated, the likelihood of compression of healthy lung tissue with diseased tissue must be left out of consideration. The next article by the same author is on mixed infection, and the last contribution in this remarkable series of interesting papers is the doctor thesis of L. Brüll on "Dauererfolge bei Larynxtuberkulose." This article is an optimistic one and the first conclusion is certainly one which, in the opinion of most tuberculosis specialists, will seem somewhat exaggerated. He says "die Larynxtuberkulose ist in all ihren Formen dauernd heilbar." As important factors to a favorable prognosis he emphasizes the extent of the lesions in the lungs, temperature, and hereditary tendencies. One of his most gratifying conclusions is that the therapeutic nihilismus in tuberculosis of the larynx has no justification. The young and gifted author was not privileged to see his article in print. A sudden death terminated what promised to be a brilliant career. His chief, Dr. Schröder, revised the article for publication.

Ueber Säuglingsernährung. Von Dr. Ernst Schloss. Mit 59 Kurven im Text und auf 3 Tafeln. Price 6 marks. Berlin: Verlag von S. Karger, 1912.

This is an interesting discussion of the subject of infant feeding, chiefly from the viewpoint of the modern development of this subject in Germany. The chapter headings indicate the scope and content of the entire work. These headings are as follows: The former methods of artificial feeding and their tendency; the problem of artificial feeding in theory and experiment; the practical consequences; the technique of feeding; the criteria of the value of feeding methods; the results of infant feeding; the dependence of results of infant feeding upon external conditions; the influence of summer heat upon the course of nutrition; nutrition and infection; nutrition and constitution; and the course of development.

A Clinical Manual of the Malformations and Congenital Diseases of the Fetus. By Professor Dr. R. Birnbaum, Chief Physician to the University Clinic for Women at Göttingen. Translated and annotated by G. Blacker, M.D., B.S., F.R.C.P., F.R.C.S., Obstetric Physician to University College Hospital and the Great Northern Central Hospital; Teacher of Practical Midwifery at University College Hospital Medical School, etc. With 58 illustrations in the text and 8 plates. Philadelphia: P. Blakiston's Son & Co., 1912.

It is correctly stated by the author in the preface to this volume that "malformations and congenital diseases are of interest from several points of view; thus they have an anatomical, pathological, physiological, clinical—more especially in relation to surgery and obstetrics—and medicolegal importance." For these reasons the present volume which represents the first attempt, at any rate in the English language, to present a full discussion of the clinical aspect of congenital malformations, is a most valuable contribution to medical knowledge. It contains a comprehensive survey of the literature of the subject, in addition to the author's own extensive observations. The subject is presented in an interesting manner, and particularly with reference to its practical applications. It is well written, and the literary skill of the translator, editor, and teacher is evident on every page. To the pediatrist, to the obstetrician, to the surgeon, and also to the general practitioner this volume may be recommended without reserve as a most valuable one.

# Society Reports.

## REPORTS FROM THE MONDAY CONFERENCES OF THE NEUROLOGICAL INSTITUTE OF NEW YORK.

### FIRST DIVISION—DR. JOSEPH COLLINS.

**Juvenile Tabes.**—Dr. JOSEPH COLLINS presented the following case: The patient, a little girl five years old, entered the Neurological Institute on August 15, 1912. The story that her mother related was that she was a full term child, born, however, as the result of a very difficult labor which lasted four days. She was breast fed until she was nine months old. She learned to walk at ten months, and began to talk shortly afterwards. Until her third year, when the illness for which she was brought to the hospital developed, she seemed to have had good health. She then had an attack of convulsions following, apparently, a fit of anger. These convulsions, which are now typically epileptical in character and which apparently have always been of the same kind, occur with varying frequency, sometimes once a day, sometimes a month apart. Her mother says she first becomes confused, then her face pales, her head turns to the right, she bites the tongue, then falls, and the limbs stiffen out equally on both sides. There are no clonic movements. There is complete loss of consciousness for about five minutes; she then starts to cry and can get up and run about. After she had been having these attacks for about a year she was seized with the measles and was sick for two weeks. It was noted that after she got up from the attack of measles, she did not walk securely. Nevertheless, she kept about for three days, then she refused to walk, and when she attempted to do so she staggered and reeled most insecurely. It is for this difficulty in walking, in standing, and of inability to control the action of her bladder, that she was brought to the hospital; but in addition to these symptoms, she has difficulty of hearing which seems to have followed complaint of noises in both ears, especially in the right ear, which came on about six months after her ataxic symptoms and which followed a yellowish discharge from the right ear. Six months after this discharge the parents noticed that she was quite deaf and this has increased in intensity; after it there has been a corresponding shrinkage of the patient's speech.

To summarize briefly: Good health until two years of age when convulsions of an epileptic character occurred. Then, after a severe attack of measles (April 27, 1911), profound ataxia. Inability to walk until June 9, 1911, when she gradually learned to walk, as a baby does. In January, 1911, pain in the ears followed by prurient discharge in August, 1911, by marked deafness and by shrinkage in speech.

Physical examination reveals: (1) Profound ataxia; (2) Argyl-Robertson pupils; (3) Absence of the tendon jerks; (4) Profound loss of deep sensibility; (5) Distinct hypotonus of the lower extremities, and to a lesser extent of the upper; (6) Profound anesthesia and analgesia over the entire body and below the nipples.

In other words, she has all of the classical symptoms and signs of tabes. But the diagnosis is not corroborated by the laboratory findings. The Wassermann reaction of the blood serum is negative, and both the chemical and the microscopical examinations of the cerebrospinal fluid seem to be negative. This, however, is not so astonishing as the fact that her father, her mother, her sister, and a brother show a strongly positive Wassermann reaction of the blood which, by the way, it may be said, has now destroyed in the entire family any salvarsan therapy. That the tabetic process in this child had its origin in the luetic infection despite the negative findings of the cerebrospinal fluid may readily be admitted. One can easily imagine that the activity of the poison ceased to exist in giving birth to the structural disease of the posterior columns when our ignorance led us to posit an hypothesis which set forth that such diseases as tabes and paresis were parasyphilitic diseases, *i.e.* diseases that developed after the luetic infection had ceased to exist as such. We taught that the virus lost its identity in giving rise to the diseases. We further taught that luetic disease was characterized by a most strikingly characteristic pathological process. We now know that although that may be in a large measure true, it is not the *whole* truth, and that the syphilitic reaction in the tissues by no means invariably causes a round cell accumulation which constitutes gummatous infiltration, which it was formerly thought to do. On the contrary, there is a syphilitic pathological process that is not to be identified with what is currently believed to be the classical pathological process. It is to be hoped that histological study of posterior roots and spinal cords of very early cases of tabes in conjunction with study of the cerebrospinal fluid may reveal what these early syphilitic lesions are.

Certain it is that the occurrence of infantile tabes in a patient in whom there is a negative condition of the blood and cerebrospinal fluid, so far as the Wassermann reaction is concerned, is an extremely interesting one.

It is interesting to inquire what the attack of convulsions that this child had for a year antedating the clinical manifestations of her tabes, and the periodical febrile attacks which she had during the summer of 1911, that is, after her attack of measles, were dependent upon. During that time her blood was examined for malarial plasmodia by her physician in Pennsylvania, who was then taking care of her, although she lived in a mountainous district where malaria was said not to occur, and no plasmodia were found. It is quite possible that the child's attacks, both epileptic and febrile, may be construed as dependent upon syphilitic infection.

### SECOND DIVISION—DR. FREDERICK PETERSON.

**Fibrosarcoma of Cervical Spine Producing Paralysis of All Four Limbs—Cured by Operation.**—Dr. FOSTER KENNEDY showed the following case: L. H., female, aged 12 years. Admitted to New York Neurological Institute on May 15, 1912, complaining of paralysis of the lower and marked weakness of the upper extremities. In May, 1911, after unusual exertion, she noticed she tripped with the right foot. A week later there was a definite weakness in the right leg, which felt heavy and frequently dragged in walking. This was progressive and in three months was also present to a less evident degree in the left leg. Occasional pain in inner side of right thigh and in the right shoulder.

In September, 1911, the weakness in the right hand and arm was reported as progressive.

In February, 1912, there was progressive weakness in the left hand and arm, together with frequent reflex jerking of the arms and legs. No sphincter trouble. There was a subjective sensation of numbness and heaviness in all four limbs and in the trunk almost to the clavicular level.

Examination: Cranial nerves normal. Motor system: Arms—The hands can only feebly be closed and show hyperextension in this movement at each wrist. There is atrophy of the intrinsic hand muscles and of the triceps on each side. Both deltoids are much enfeebled and wasted. Abdominal recti muscles are almost or quite palsied. Lower extremities: Complete palsy of left leg for all movements. On the right side a very slight degree of knee flexion can be performed.

Sensory system: Loss of power to appreciate pain, thermic, and touch stimuli below the level of the third dorsal vertebra, and also along the ulnar borders of both

upper extremities controlled by the eighth cervical and first and second dorsal spinal segments. Deep muscle pain sense is retained though slightly diminished in legs.

Sense of position is lost in the two ulnar fingers, right and left, and diminished in the toes. There is astereognosis in both hands.

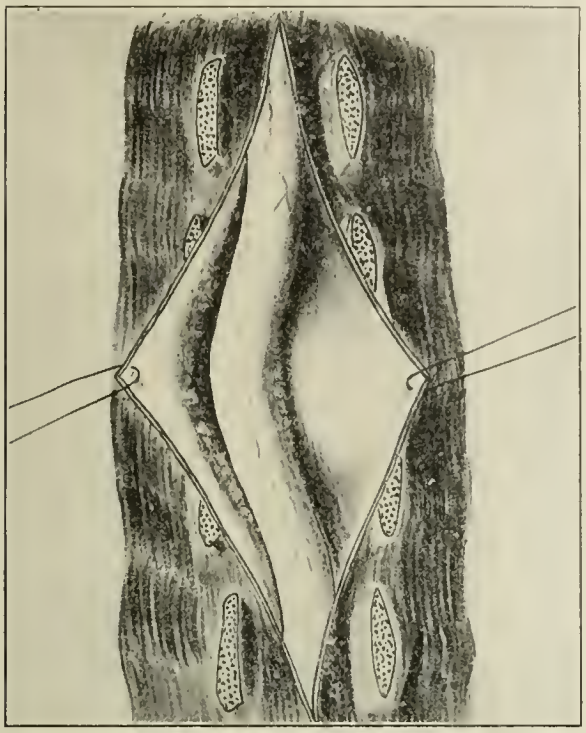


FIG. 1.—Fibrosarcoma of the cervical spine; view of the cord on opening the theca, showing the distortion.

Reflexes: Arm jerks absent; abdominal reflexes absent; knee jerks exaggerated, the right more than the left; ankle jerks exaggerated equally in the two sides; ankle clonus greater in the right than in the left side; plantars, both of extensor type; no sphincter trouble.

Cerebrospinal fluid: Wassermann reaction negative, cells absent, globulin content increased.

Skiagraph by Dr. Lewis Cole showed a very definite destruction of the four lower cervical vertebræ in the region of the intervertebral foramina. In spite of this there was no tenderness nor rigidity in the cervical spine, nor was any pain produced by cervical movements.

On May 31, Dr. Elsberg operated. The spines and laminæ of the sixth and seventh cervical and first dorsal vertebræ were removed. The theca was enormously distended and when incised cerebrospinal fluid spurted out to the distance of one foot. The cord was congested and pushed to the left. No tumor was found within the theca. The spines and laminæ of the fifth cervical segment were then removed, and the cord in its membranes pulled over strongly to the left. This procedure resulted in exposing an extradural tumor, about 4 x 3 cm. in size, lying in the right-hand corner of the anterior part of the spinal canal. Into this new growth ran the C. 7 and C. 8 posterior roots. These were cut. In its removal the tumor ruptured and had in consequence to be taken away with a sharp spoon leaving a large bone cavity produced by pressure erosion. Pathological report: Fibrosarcoma.

For a week following operation there was complete abolition of the knee and ankle jerks. Frequent incontinence of urine and feces. Complete palsy of both tricep muscles and acute flexion of the elbows by the unantagonized action of the biceps on each side. Sensory condition as before.

June 23.—Occasional incontinence of urine. No rectal trouble. Power beginning to return in both lower extremities, the left better than right. Grasps improving. Sensory condition, as before as regards distribution but only relative in degree for all forms. Knee and ankle jerks increased.

August.—Patient now able to stand and walk a few steps with help. No sphincter trouble. Sensory disturbance almost entirely absent.

November.—Patient can walk and run unaided. No sensory disturbance. No sphincter trouble. Power good in both hands. Some atrophy in intrinsic muscles of right hand still present.

THIRD DIVISION—DR. PEARCE BAILEY.

**Myasthenia Gravis.**—Dr. BAILEY presented the following case, which showed that between the attacks of this disease functional activity of the affected muscles may be restored, and the bulbar symptoms may be absent.

The patient, a young German woman, 20 years of age, gave no history significant as to heredity, and, with the exception of an attack of scarlet fever at the age of 12, and diphtheria (antitoxin) in February, 1911, a few months before the onset of the present trouble, the patient herself had always been well in every respect. The disease was ushered in by fatigue in the muscles of the arms and legs especially in the movements of rising and stooping, and movements which required the raising of the arms above the head. There was no spontaneous pain, but the limbs and back felt so tired at times that it amounted to pain. The left arm and leg were always the worst. This fatigue was markedly increased by the use of the muscles. She felt fairly well in the mornings, but as the day wore on she would become so weak, sometimes as early as by 12, noon, that she would have to go to bed. The condition progressed; objects that she lifted from shelves would drop from her hands and she would fall down in walking.

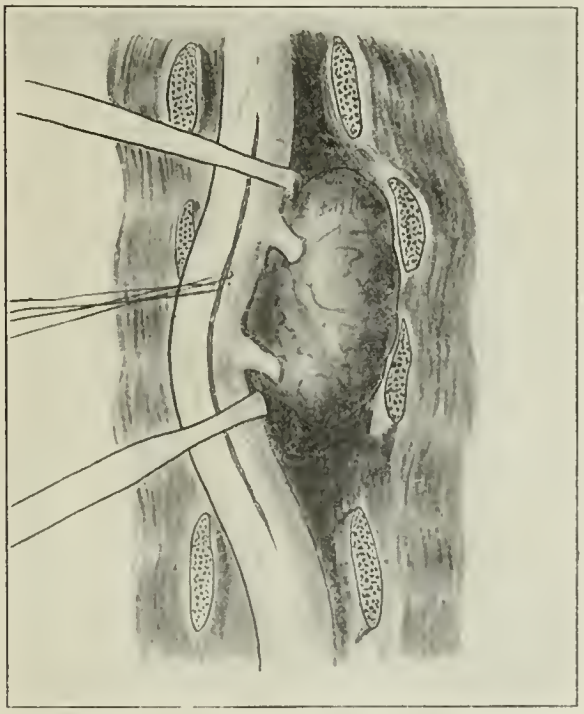

FIG. 2—Dural sac retracted to show the tumor in its bed in the spinal canal. In this case the *x*-ray picture showed a marked enlargement of the canal at the level of the tumor, due to absorption of bone. (Drawn by Dr. Elsberg after operation.)

On admission she showed marked weakness of the muscles of the shoulder and hip girdles. She could not raise the arms horizontally, and in walking she waddled in the way characteristic of loss of power of the muscles about the hip, as is seen in juvenile dystrophy. She could not

get up from the floor unaided. She could stand and walk on her heels and toes, and had a strong, firm grip, and could execute these movements in rapid succession without evidence of fatigue, but in movements actuated by the muscles springing from the trunk, the fatigue was extreme. If she persisted in walking, she would fall, and by repeatedly raising the arms from the side she soon lost the power to raise them at all. This distribution of the motor weakness deceived us at first so that we thought the case might be one of muscular dystrophy, as the distribution of fatigue corresponded exactly with the weakness of muscular dystrophy. This view, however, was later abandoned. Another feature which hindered the diagnosis at first was that there was no involvement of any of the muscles supplied by the cranial nerves, no atrophy, no myasthenic reaction, no disturbances of sensation, no glandular enlargements. On her first admission the knee jerks were diminished, but soon became normal. Examinations of the blood, serum, and cerebrospinal fluid were negative, and the stomach contents, intestinal contents, and renal excretions were all normal. Chloride estimations were made, as the result of which it was discovered that the amount of chlorides was much below normal.

This patient was in the hospital twice, and after her first admission, on no special medication, she improved very rapidly, and left the hospital in six weeks, walking without a limp, using the arms freely, and feeling as strong as ever. She soon relapsed, and was readmitted in even a worse condition than before.

The case is important, first, on account of the difficulty it presented, until all the conditions were known, in being differentiated from a case of Erb's juvenile dystrophy; second, from the fact that while under our observation there was never any involvement of the cranial nerves and it will be remembered that this symptom is so common in myasthenia gravis that one of the names for the condition is "pseudo bulbar palsy"; third, negative results of careful chemical examinations; fourth, complete though temporary restoration of muscular power, with total disappearance of what had been a serious disability.

## MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

*Stated Meeting, Held November* 18, 1912.

The President, Dr. Reynold Webb Wilcox, in the Chair.

**A Simplified Ether Inhaler.**—Dr. A. Ernest Gallant presented this. He said it had for its basis the Allis inhaler, which was first modified by himself in 1892, when he replaced the threaded bandage with a diaphragm of gauze on the lower end and inserted a piece of loose gauze within the cavity of the frame upon which the ether was poured. This loose gauze was found to absorb the ether, but did not really give it up for evaporation and warming. (Medical Record, December 30, 1899.) In order to meet the needed requirements the inhaler had been modified and improved by (a) making the ovoid drum without the lateral slits; (b) covering both ends of the drum with gauze drum-heads; (c) lengthening the rubber sheath and adding to the left side of the top a weighted envelope-like flap; (d) placing a cordlike ridge inside the sheath to prevent the drum from sliding down upon the patient's nose. The inhaler was of simple construction, consisting of a drum, which might be made of tin, sheet iron, water pipe, galvanized iron, or even cardboard, moulded into an ovoid, with a rolled edge at top and bottom, and with its ends covered by drum-heads of six thicknesses of sterile absorbent gauze, secured in place by string, stitching, or surgeons' rubber plaster; the drum being inserted within a long rubber sleeve or sheath. The tightly stretched gauze drum-heads were preferred to loose gauze, or any other material, because they offered a larger and more accessible evaporating surface; while the ether, poured in from the top, was rapidly warmed, in passing through the hollow drum, before it entered the respiratory tract of the patient. Thus it was more readily absorbed, and it did not irritate the bronchi and lung tissue, as was too often the case with unwarmed ether; thereby securing freedom from post-operative bronchitis and pneumonia—sequelæ which had never followed the use of this inhaler. The rubber sleeve, which was 6 by 9½ inches in size, had an envelope-like flap at the top, which could be swung back to open the cone when beginning the administration or pouring in fresh ether, and tipped over to the left to close the top when it was deemed advisable to prevent the escape of ether, secure a deeper degree of anesthesia, or raise the temperature of the ether by confining the hot breath of the patient more closely within the inhaler. The flap was furnished with a metal plate to act as a weight and leave the right hand of the etherizer free, but this was not intended to close the top so completely as to deprive the patient of a liberal supply of fresh air, though it prevented the escape of warm ether. The temperature of ether-air inhaled during anesthesia had been found by Joss to average 33° F. below the temperature of the room, and the difference might at times be even as great as 44° F. Having referred to the evils resulting from chilling the air-passages, this author had stated that the problem now was to find some way to counteract the refrigerating action of the ether and warm the air as it was inhaled. This, Dr. Gallant said, he believed had been accomplished by his inhaler, which had stood the test of fourteen years' use in hospital and private practice, and in the hands of many different individuals. For chloroform or ether and chloroform combination inhalation, the quantity of chloroform required was reduced to nearly one-third of that called for by the Esmark or other apparatus, a result which he attributed to the warming of the chloroform. Of course, the top should always be kept open when chloroform was used. Essence of orange, advocated by J. T. Gwathmey for the beginning of anesthesia, could be readily employed with this inhaler, and a few drops of an alcoholic solution of the essence poured on the drum-head was found to disguise completely the odor of ether. When this was used the patient passed into unconsciousness without any preliminary stage of excitement, the anesthesia was easily maintained with less than one-half the quantity of ether required by the usual methods, and, except in very rare instances, the patient quickly and comfortably recovered consciousness without vomiting or nausea. The simplicity of the use of this inhaler could be best appreciated when it was understood that the patient usually took the inhaler in his own hands and administered the ether to himself until his hands relaxed, when the anesthetist took charge of it. The ether could be replenished either by pouring a drachm or two into the open top of the inhaler or by means of the "drop method," which was less safe because the ether could not be brought to as high a temperature before entering the lungs.

**How to Prevent Uric Acid by Phenol.**—Dr. William Henry Porter read this paper. In former papers of his, he said, it had been shown that uric acid was formed normally in the secretory cells lining the uriniferous tubules, and that it was its proteid antecedent only which existed in the blood. Uric acid, as all knew, was one of the normal end-products of the oxidation reduction of the protein molecule and, as such, was one of the essential products carrying nitrogen out of the body. When all the uric acid was transformed into sodium urate and the acid sodium phosphate, as a result of its coming in contact with the neutral sodium phosphate in the lumen of the uriferous tubule, the system was working normally so far as this end-product was concerned, and no free uric acid escaped from the tubules. When, however, this acid was formed in larger amount than could be converted into urates, it was found free in the urine, and then became a pathological product. When thus over-produced, it often massed together, with the formation of large or small calculi. It was not the purpose of the paper to discuss the best mode of combatting the overproduction of uric acid, but to elucidate the method by which phenol prevents the massing together of the uric acid crystals, and thus intercepts the formation of uric acid calculi. Many years ago it became a well established clinical fact that one or two grains of pure phenol, given three times a day, would prevent the formation of such calculi, and also arrest the recurring attacks of renal colic. How this empirical result could be explained upon a logical and scientific basis was long an unsettled problem; but, with our ever increasing knowledge of the chemical mutations which regularly take place in the alimentary canal and urinary channels, it had now become possible to formulate a theory which would fully explain this valuable therapeutic action of phenol. Phenol, in common with many other substances, contained replaceable hydrogen atoms; which circumstance enabled it to unite with basic substances and form carbolates of the same. Under the same laws which had been laid down for the mineral acids, the action of carbolic acid could be sim-

ilarly elucidated. The phenol, when it reached the stomach and intestinal canal, reacted upon the sodium, potassium, and other saline constituents of the foodstuffs in a manner similar to the action of the mineral acids, and formed carbolates of sodium, potassium, etc. The most likely combination was with the sodium compounds, because these were the most abundant. The carbolate thus formed could be absorbed and taken into the bloodstream without precipitating the proteid elements, and in an alkaline menstruum such as the blood and the fluids of the tissues there was no occasion for it to be decomposed, with the liberation of free carbolic acid. In accordance with the law that all inorganic compounds act in the organism alone by virtue of their mechanical presence, it seemed reasonable to assume the same for the "pseudo-organic" class of compounds to which carbolic acid belonged, namely, that the carbolate salts were not decomposed in the blood, and that they were powerful irritants to the system—equal in this respect to most of the poisons of the strictly inorganic substances. While these phenol compounds were not in the strict sense mineral substances, so far as their action, both experimental and clinical, went to prove, they followed the same law of action governing the purely mineral compounds, rather than those governing organic elements. It was a well-known fact that when phenol was taken into the animal organism in considerable quantities the coagulating power of the blood was retarded, and this presumedly was due to the saline form of the carbolates formed in the alimentary canal, since free phenol, when brought in direct contact with the blood, coagulated it. In view of these various observations, it seemed entirely logical to assert that the mechanical presence of the carbolates in the circulating blood can, like that of other known saline compounds, so affect the proteid bodies contained in the blood that the coagulating power of the latter is decreased or altogether arrested. Further, it might be supposed that the presence of the carbolate so changed the metabolism in general, in connection with the abnormal conditions named, that the final product of oxidation tended to become urea, instead of the lower product, uric acid. This, however, could not be the actual method by which the formation of uric acid calculi was so suddenly arrested and the super-acidity of the urine changed to a less intensely acid reaction; for the total quantity of uric acid formed and to be eliminated from the system daily could be reduced only by cutting down the amount of foodstuffs ingested or by increasing the intake and the distribution, throughout the system, of oxygen. The carbolates, after having circulated through the system, passed out of the blood by a process of filtration through the walls of the capillary blood vessels constituting the Malpighian tufts in the kidney in a manner similar to the escape from the blood stream of all the mineral salts. From this point the phenol salts passed down the lumen of the uriniferous tubules until they reached the location at which uric acid was constantly being formed and given off by the excretory epithelium into the tubules. Here they came in contact with the free uric acid, and, the two reacting upon each other, decomposition of the salt ensued, resulting, in the case of the sodium carbolate, in the formation of a somewhat soluble sodium urate and the liberation of carbolic acid. It was this formation of sodium urate which prevented the transmutation of the over-produced uric acid into calculi (thus dispersing the painful symptoms almost as if by magic), and this action of the carbolic acid was rendered possible by the fact that the foodstuffs contained a surplus of sodium compounds which ordinarily remained unabsorbed and passed out of the alimentary canal with the feces. In the natural working of the digestive process the normal sodium phosphate was acted upon by the gastric hydrochloric acid, with the formation of disodium hydrogen phosphate and sodium chloride; but when phenol was administered some of the surplus soda in the foodstuffs in the alimentary canal was acted upon by this agent, with the formation of disodic phosphate and of sodium carbolate, instead of sodium chloride. The carbolates were readily absorbed and passed to the kidneys, where they were promptly decomposed by the uric acid, thus using up the over-production of the latter, and thereby preventing its deposition, as mentioned, in the form of calculi. When the amount of phenol was small, and the elimination effected somewhat slowly, the carbolic odor was not perceptible in the urine, but when the quantity was considerable, this at once became apparent. Furthermore, the presence of phenol in the urine could be detected chemically, and thus the laws of chemistry and physiology furnished a complete explanation for the good clinical results which had so frequently been obtained from the administration of phenol in conditions in which uric acid was being over-produced. This also helped to clear up many of the unexplained phenomena associated with phenol poisoning when the drug was used as a surgical dressing. Ordinarily, in a wound, this agent coagulated the proteid substances with which it came in contact, and thus prevented its own further entrance into the general circulation; but when it was used in large amounts, or remained in quantity for some time in the dependent cavity of a wound, it might unite with the sodium or other mineral compounds in the fluid exudations, and thus render possible its access to the circulation. Now, if carbolates were absorbed and passed to the kidneys more rapidly than they could be eliminated with safety by these organs, they, by virtue of their irritating properties and their consequent ability to disturb proteid transmutations within the body, would cause a disintegration of the red blood corpuscles. As a result, the pigment contained in the hemoglobin was set free, and an acute and often fatal hemoglobinuria produced.

**Infant Feeding in Its Relation to Infant Mortality.**—Dr. Joseph E. Winters made an address on this subject. In this he pointed out the enormous mortality now prevailing in the first months of life, and contended that this could in large measure be prevented if mothers universally could be induced to nurse their infants. That women could, as a rule, be brought to do this had been shown in some of the European schools for midwives. The fact that mothers did not nurse their infants more generally was due to a very large extent to the obstetricians and midwives, and the time had now come when there should be a change in this respect. The act of parturition was only half completed when the child was delivered, and it ought to be realized that it was as essential to the mother as to the child that the latter should be nursed at the breast during the purperium. At the end of utero-gestation the uterus and its blood-vessels were enormously enlarged, and in order that involution should be successfully accomplished it was necessary that the organ should contract powerfully and continuously. This could be secured only by the stimulus afforded by the act of nursing. Every time that the infant took the breast the uterus could be felt to contract firmly, and by this nursing, post-partum hemorrhage could be prevented and perfect involution effected. It could thus be seen that most of the evils, such as uterine displacements, etc., which now make women chronic sufferers and bring them to the gynecologists could be avoided if nursing at the breast were more generally practised. As to the infant, the colostrum was exactly what it required at the time, and the green stools which it often caused were entirely physiological. The vomiting not infrequently observed was really of no consequence. It was a common practice to give the newborn infant water, but this was a mistake, as it made it refuse to take the breast. It should be put to the breast just as soon as the mother had received proper attention, and during the colostrum period it should be allowed to nurse as often and as long as it would. It was not necessary that breast milk should be the exclusive food of the child for a very long period, and as early as the second month it might be allowed one bottle of properly prepared cows' milk with advantage. In this way the mother could have an undisturbed night's repose, and the weaning could be gradually and easily accomplished. As a rule, women nursed their infants for much too long a time. The only substitute for mothers' milk was cows' milk, properly modified. The young infant required a strictly animal food, and proprietary foods were injurious. Physiology was the keynote of infant feeding. The food should be of the composition of the body, and that which he had elaborated from the top half-ounce of cream was based strictly upon physiological principles and was identical with mothers' milk. The protein was flocculent, and would thus pass freely through the extremely narrow orifice of the infant's pylorus.

Dr. Harold Capron Bailey said he had been especially pleased to be asked to discuss Dr. Winters' paper because he felt that the obstetrician should be more closely associated with the pediatrist. The mortality in early infancy was appalling, and we now recognized that the accomplishment of breast feeding was the greatest factor in its reduction. In fact, breast feeding for only a few days was helpful, and every added week of such feeding would reduce the mortality. If a woman could nurse her child but two or three times a day, statistics showed that even this amount of breast milk was of value. It had been recently pointed out that the colostrum conferred immunity to the child for certain diseases the mother had had. Practically every mother could nurse her baby. Contrary to the general opinion, milk constituents were but little affected by the food taken by the mother. The

sugar content was high throughout, and the protein increased in a definite ratio which was undisturbed by a large amount of protein in the diet. The quantity was variable, and many children needed extra feedings from prepared formulae. Midwives, practitioners, and obstetricians were prone to take the baby away from the breast, which furnished a physiological food, and place it on the bottle; food prepared according to chemical formulæ. As to the feasibility of persuading women to nurse their babies, of 300 women delivered at the newly organized School for Midwives in this city, all but one nursed during her stay in the hospital. Between 10 and 15 per cent. of the babies had to have extra feedings because of their failure to gain in weight on the amount of nourishment furnished by the mother. Practically the only indications for feeding from formulae from the start were tuberculosis of the mother and undeveloped breasts with inverted nipples. Eclampsia and breast infections caused temporary undesirability of nursing. As to the advantage of top milk feeding, Dr. Winters' statements were upheld by the work of Schwartz, who found the fat globules surrounded by a periglobular substance similar to casein which prevented the fat globules from flowing together. Pressure broke up this physical combination. Undoubtedly the centrifuge acted in this way. It was estimated that 7 per cent. of the calories provided should be proteid, in order to furnish nitrogen for the building of the body. Nature provided about this amount in breast milk. Any additional protein, even if digested, was not an economical food for the body. Milk sugar, as far as we knew, was chemically the same in human and in cows' milk. In human milk there was a large amount of this substance—between 6 and 7 per cent., and from the beginning to the end of lactation. It would seem highly improper, from a physiological standpoint, to use any other carbohydrate, such as cane sugar, malt sugar, or malt soup. We should remember that the sugar gives the major number of calories in the formulae, and any reduction in the amount of this substance had to be compensated by large amounts of protein and fat.

Dr. Franklin Welker said that from the standpoint of the general practitioner it was questionable whether we paid sufficient attention to the breasts of women during pregnancy. It was the sacred duty of the mother to nurse her child, and it devolved upon her medical attendant to see that she was in every way prepared to carry out this duty. What could be accomplished in this direction had been well shown at the school of midwives in Stuttgart, where the percentage of mothers nursing their infants had been raised from 23 to 100 per cent. It was work of this kind which told in the reduction of infant mortality. There was much to be thankful to Dr. Winters for, for what he had already accomplished; but there was still much to be done. He remembered being much impressed by a monograph by Dr. Winters, published in 1901, in which he stated that an artificial food to be successful must (1) contain all the constituents of mothers' milk; (2) must have the constituents in the same proportion; (3) must contain nothing not found in human milk; (4) must be of animal origin; (5) must be fresh. In other words, cows' milk was the only substitute for the infants' natural food. His personal experience with pure raw milk, modified in accordance with Dr. Winters' directions, had been very gratifying. The success of the method depended largely, however, on the faithfulness with which the mother or nurse carried out its details.

Dr. William Shannon said that for many years he had been familiar with Dr. Winters' work, both at the college and elsewhere, and he could testify to the marked success of his methods, especially in his own hands. Others, perhaps, did not meet with quite the same success, because they did not thoroughly understand his plan of artificial feeding, or did not carry out its details carefully enough, or because they did not give it a sufficiently long trial. We were all agreed as to the great desirability of maternal nursing; but in cases where this was impossible it became necessary to get a substitute for the mother's milk, and cows' milk was recognized as the best food for this purpose. The constituents were not, however, identical in their proportions. There was a marked difference in the proteid content, and here, apparently, was where all the difficulty lay. He had never seen a perfectly well-fed baby which was raised on proteid; a certain amount of fat was essential for the nutrition of the infant. Dr. Winters' formulae certainly approximated mothers' milk more nearly than any others that he knew of. As to the sugar to be employed in artificial feeding, he had personally found malt sugar very satisfactory. While it was true that this form of sugar was not a constituent of human milk, it was a fact that it was met with normally in the intestinal canal, in the blood, and in the liver and other organs.

Dr. William D. Tyrrell said there was but one perfect food for the new-born infant, and that was mothers' milk. Moreover he believed it was practicable to have every mother (or at least 99 per cent. of mothers) nurse her child. Active tuberculosis in the mother was really the only contraindication to nursing. Breast milk contained certain protective bodies which were not to be found in any artificial food, and this constituted one great element of safety. It seemed evident that a marked reduction in infant mortality might be effected if, in the first place, mothers generally could be induced to nurse their children for at least one, two, or three months, and if, second, a proper artificial food were selected in the few cases where this was impracticable. In regard to the amount of fat in such a food, 490 was not excessive, for this was normal. An ample fat content was, indeed, a physiological necessity. This kind of food was a source of energy. Fat entered into the composition of the protoplasm of every living cell, and it was therefore essential for the growth of the body; while, with a high percentage of fat, only a minimum of proteins was required. Excess of both protein and sugar was productive only of evil. Furthermore, excess of fat protected the protein already in the cells. For these reasons, therefore, he knew of no method of artificial feeding which produced such uniformly good results, in such a large percentage of cases, as that of Dr. Winters.

Mr. Lawrence said that Dr. Winters, in his remarks, had condemned pasteurization, and he would like to inquire his reasons for this.

Dr. J. Milton Mabbott said that he was much pleased to hear Dr. Winters speak so strongly of the marked benefit on the mother to be derived from nursing her infant. While on this part of his subject he might perhaps well have gone a little further and referred to the necessity of attention to the nipples during pregnancy, to prepare them for nursing. In many women the nipples were quite unfit for this function, and yet it was entirely feasible, as well as very important, to get them in proper condition by the time the child was born. Some time ago he had published an article on this subject, and all were no doubt familiar with the means for accomplishing the desired purpose. In regard to nursing, therefore, we ought to have in mind four things: (1) The preparation of the nipples; (2) immediate nursing—not waiting for twelve hours, as recommended by some authorities; (3) the withholding of water from the new-born infant. In this particular he had to confess that he had often been guilty of giving one or two teaspoonfuls of boiled water to the baby, but he suspected that Dr. Winters was correct; (4) where a substitute for the mother's milk was required there could be no doubt that the top milk advised by Dr. Winters was by far the best in the earliest days of the infant's life. Many babies would, of course, get along on other artificial foods; but wherever there was a question of the survival of a baby, it should certainly be placed on the best without delay.

Dr. A. C. Palmateer said he would like to ask Dr. Winters four questions: (1) What form of sugar he used, and why: (2) at what time he would advise weaning babies; (3) if vomiting were physiological. Personally he had to confess that he had experienced some trouble from vomiting, and perhaps he had made a mistake in cutting down the periods of nursing; (4) when to introduce cereals into the diet.

Dr. Winters, in closing, said that if Mr. Lawrence would come to his clinic at Cornell Medical College some day he could practically convince him of the evils of pasteurization. There he would see, almost dead, infants which had been fed upon pasteurized milk. When extreme heat was applied to milk, as in condensing it, the product was liable to give rise to the worst form of scurvy-rickets. When the heat was not so great the milk would still cause scurvy-rickets. This was the case with sterilized milk, and some years ago, when sterilization came into vogue generally, there was among infants an immense amount of scurvy, which was almost invariably diagnosed as rheumatism. Sir Thomas Barlow was among the first to describe the condition, and it became known as Barlow's disease. The same was true, in a lesser degree, of pasteurization. Already this autumn he had seen two cases of scurvy from pasteurized milk, and he could not but regard the present widespread predilection for this kind of milk as a positive calamity. No one ever saw a plump and perfectly normal baby which had been fed for a prolonged period on pasteurized milk. At a single clinic he had had no less than four infants with practically no life in them from this cause. As to withholding water from the new-born child, he did not mean to lay this down as an absolute rule; but it was true, as he had said, that the giving of water generally had the effect of making it refuse to take the breast. If

it did not have the water it would be compelled to nurse. The sugar he employed was that which nature furnished, milk sugar. In his opinion there was no excuse for using malt sugar or malt soup, or, indeed, any malt preparation. It was not physiological, and physiology should be our only guide. As to the vomiting of infants, a great deal of it was due to excessive handling of the child, and as soon as this was discontinued the vomiting would cease. For the young infant he avoided all cereals absolutely, as unphysiological. As he had just said, he had but one guide in his feeding. Why should we give vegetable foodstuffs when there were no secretions which would digest them? In this matter he took his ground from the standard textbooks on physiology in this country and Europe, and therefore when certain men asserted that they had found that the young infant was capable of digesting cereal food, he did not believe them. No such statement could be found in any established work. In reply to a question from the president, Dr. Wilcox, Dr. Winters said that the top milk used varied according to the age of the baby. The method he employed had during a course of years been most carefully worked out, both practically and in the laboratory. He had tested it thoroughly in his work, and then his results had been confirmed by a series of laboratory experiments by such men as Dr. Lederle, Dr. Adriance, and Prof. Sherman. He could, therefore, speak with some confidence as to the pronounced success which had been obtained. On the other hand, neglect to consider the physical behavior of protein had led to grave errors and an immense amount of trouble in infant feeding.

## NEW YORK ACADEMY OF MEDICINE.

### SECTION ON MEDICINE.

*Stated Meeting, Held November 19, 1912.*

Dr. W. L. Niles in the Chair.

**Demonstration of Sahli's Latest Modification of the Pocket Sphygmobolometer.**—Dr. Nathaniel Bowditch Potts exhibited this instrument which was the latest modification of the one described in the last edition of his textbook, "Diagnostic Methods," English translation, second edition, page 180. The instrument now upon the market was very compact, easily applied, and convenient for clinical use. The purpose of this instrument was to obtain a measurement of the work accomplished by the individual pulse wave expressed in gram centimeters. Sahli explained that this instrument measured a dynamic force; it had no relationship to the estimation of the blood pressure which was a static conception. Dr. Potter then showed the increase of work by an individual's pulse before and after climbing a series of stairs.

Mr. Severinghaus, Department of Physics of Columbia University, discussed the principles upon which this instrument was based.

**A Case of Extreme Dilatation of the Esophagus.**—Dr. Theodore C. Janeway reported the case of a woman, forty years of age, who was admitted to the hospital April 10, 1912, and discharged April 15. She had always been healthy until her present trouble arose. She weighed about 140 pounds; her habits of eating were very irregular and about ten years ago she began to have distress immediately after eating and the feeling of a lump that would not pass on. At times she would put her finger down her throat and occasion a vomit for her relief. Occasionally she would have a week free from distress. Five years ago she took soda for the relief of her distress and with apparent success. One year ago she began to vomit more and she noticed in the vomites food that had been eaten the preceding day: there was an increase in her distress. For three months she had eaten only milk, eggs and gruels; the attempt to eat meat precipitated acute distress and vomiting. For two months she had vomited foul smelling material, but never any blood. For three weeks she had been vomiting even milk and eggs. She was constipated and had great thirst. On admission to the hospital she was extremely emaciated and weighed only 77 pounds. Her temperature, pulse and respiration were normal and blood pressure from 115 to 80 m.m. In the right interscapular region there was some relative dulness and an enfeeblement of the respiratory murmur. There were no peristaltic movements seen and some tenderness in the left epigastric region. Both kidneys were palpable. Examination of the rectum revealed some nodular masses which were hard and tender. There was a very obstinate edema of the legs. The urinary examination was negative and the examination of the blood and the stomach contents after test breakfasts led them to suspect carcinoma of the stomach. At operation the stomach was found to be absolutely normal; the gall-bladder, duodenum, pancreas, and the kidneys were normal. The colon was prolapsed and the appendix slightly nodular. The latter was removed and the examination showed that it was in process of obliteration. The patient nearly died after the operation of an indefinite pneumonic infection, but finally recovered and returned two weeks later to the medical service still vomiting constantly and emaciated to a living skeleton. Finally a complete examination was made to find if an esophageal dilatation or diverticulum might be present. Introducing the stomach tube about one-half its length several hundred cubic centimeters of fluid with food particles gushed up and the flow was accelerated by coughing and not by vomiting efforts. After washing out the esophagus completely 500 c.c. could be introduced and removed. On its introduction, gurgling sounds could be heard to the right of the sternum and when full dulness was evident here which disappeared when the esophagus was empty. At no time could the tube be made to pass the cardia, and the vomiting was evidently from a greatly dilated esophagus with stricture at the cardiac orifice. This diagnosis was confirmed by a bismuth radiograph which showed an enormous cylindrical dilatation of the esophagus, with bulbous enlargement to the lower end. Esophagoscopy a few days later showed extreme narrowing at the lower end of the esophagus, through which it was impossible to pass any catheter. Finally the patient was persuaded to submit to a gastrostomy. She weighed 74 pounds at this time. Two days after the operation feedings were begun; milk and lactose diluted with water were given every hour. The amount of food was gradually increased, beef juice, eggs, gruels, whiskey being added successively. The operation was performed in May and in September the patient weighed 125 pounds. Nothing was given by the mouth. In October a thread was successfully passed into the esophagus from the stomach. Dilatation by catheter from below, using the thread as a guide, had been carried on since and a bougie one cubic centimeter in diameter could now be passed. No food had yet been swallowed successfully through the cardia, but food introduced into the stomach at times passed up into the esophagus and was recovered in the lavage. This patient's weight had now remained stationary for a month at 123 pounds.

**A Case of Chronic Lung Abscess Cured by Artificial Pneumothorax.**—Dr. David Bovaird, Jr., reported the case of a carpenter, aged thirty-nine, who was admitted to the hospital May 27, 1912. In August the patient was suddenly taken with severe sharp pain in the right side. He went home and to bed. The next day he had chills, fever, and a severe cough which raised a moderate amount of white sputum. The pain in the side remained for ten days and then grew better, but the cough grew worse. He only expectorated a moderate amount. He remained about the house for about three months and did not believe he had any fever after the first month. At the end of this time (three months) he went to work, but did not feel strong. His cough kept up and was pretty constant. He spit up moderate amounts during the day, but most was raised during the night. When he laid down he would start coughing. At last he raised very large amounts of very foul material. His chief complaint was the severe headache, the severe cough, and the expectoration of the foul material. The diagnosis of chronic lung abscess was made and nitrogen injections were given on October 22 and 29, and November 7 and 16, 1912. The patient was discharged improved September 21, and was readmitted on October 16. The result in this case was all that could be asked for.

**Bence Jones Protein in Urine.**—Dr. Selma Grant made this demonstration.

**An Unusual Case of Oral Sepsis.**—Dr. Francis P. Kinnicutt reported this case. He said that during the past several years he had had the opportunity of observing several cases of oral sepsis. The symptoms in the form of local discomfort were often insignificant and the local signs seemed inadequate to explain the systemic disturbance. The obvious local signs might be no more than dental caries of one or several teeth, a contiguous gingivitis, and not infrequently a diffuse pyorrhea alveolaris of varying intensity. Many slight disturbances of health, as well as grave systemic disturbances, might be traced to oral sepsis. The case reported was that of Dr. G. W., 56 years of age. In August, 1911, he developed what was supposed to be a case of grippe in which both antra were said to be involved. At the end of two weeks the patient was up and doing his work, but did not feel well; he thought he had a little fever and night sweats. Two

months later he had a sharp chill and a stepladder rise in temperature to 104° F. The temperature then fell suddenly and remained normal for two weeks. From this time there was continuous fever of the remittent type, the daily range being 99° in the morning to 103° F. in the afternoon. There were associated general neuralgic pains, slight epistaxis, frequent slight chills, occasional sharp ones, frequent night sweats, and marked loss of weight (twenty pounds). The liver gradually enlarged and was finally palpable five centimeters below the costal arch. The spleen was also easily palpable considerably below the costal arch. It was thought that he had typhoid fever, though the Widal test was negative. A very careful examination of the patient in the eighth week of his illness was entirely negative beyond showing the hepatic and splenic enlargements referred to. Finally examination of the mouth revealed very considerable dental caries, a moderate amount of gingivitis, and a diffuse pyorrhea alveolaris. The teeth and gums were cleaned, the bacterial deposits removed, and two markedly carious teeth extracted. A slight improvement followed, but was not maintained. A second careful physical examination by Dr. Walter B. James was likewise negative, revealing no other signs than those described. The oral origin of the systemic symptoms was reaffirmed and fifteen teeth were extracted. Five days later the temperature became normal, and, except for a slight rise for two or three days accompanying prolonged and painful oral treatments, a rapid subsidence of all constitutional symptoms occurred. There was an equally rapid disappearance of the hepatic and splenic enlargements. Dr. Kinnicutt expressed himself as firmly convinced that a certain proportion of cases of so-called pernicious anemia were in reality cases of septic anemia of oral origin.

**The Pulse Deficit in Auricular Fibrillation.**—Dr. T. Stuart Hart said that on account of the complete irregularity of the ventricular action in auricular fibrillation and the consequent variations in intervals, force, and volume of the pulse wave the following points were of clinical importance: (1) The examination of the radial pulse alone was not a safe guide to the condition of the patient or the results of therapeutic procedures. (2) Valuable data might be obtained by counting the apex beats by the auscultatory method and comparing this with the pulse rate as obtained by palpation of the radial. They had named this difference the *"Pulse Deficit."* In grave cardiac insufficiency of auricular fibrillation the *"Pulse Deficit"* might be 50 or 60. Under successful treatment the rate of the heart was slowed and the "Pulse Deficit" was reduced or disappears. This was a better guide to the dosage of digitalis than that of the production of nausea and vomiting or the appearance of the coupled rhythm. (3) The usual method of estimating the systolic blood pressure, by noting the highest brachial pressure at which a pulse wave below the point of compression could be detected, was entirely fallacious in cases of auricular fibrillation on account of the ever varying presence of the successive pulse beats. (4) They had devised a method of estimating approximately the true systolic blood pressure of the individual with auricular fibrillation. By means of a cuff on the brachial artery the pressure was raised to a point where the most forcible beats could be detected at the wrist; the number of these beats was counted for one minute; the pressure was then lowered in stages of 10 mm. each (counting each stage for one minute) until the same number of pulse waves reached the wrist as could be obtained without any brachial pressure. The average pressure was then estimated by multiplying the several pressures by the number of beats reaching the wrist at the several pressures, adding together and dividing by the heart beats per minute as detected by auscultation of the apex. The resultant figure they had termed the *"Average Systolic Blood Pressure."* Working in this way they had been able to demonstrate the increase in blood pressure with the improvement of the patient and to show, contrary to the statement of Mackenzie, that digitalis really did increase the blood pressure in auricular fibrillation.

**Typhoid Vaccination.**—Dr. Albert Lamb read this paper and said that one year ago last May began the work of vaccinating the nurses at the Presbyterian Hospital against typhoid fever. Before starting the work the back records were investigated in order to find out how frequent the disease had been. Covering a period of twenty years beginning with 1892, the year the training school was started, it was found that there had been fifty-two cases of the disease among the nurses, doctors and orderlies. Only those cases were included where there was a definite history of recent exposure to typhoid while caring for patients. Thus there was an average of between two and three cases of preventable typhoid a year (2.6 per cent.). There were four deaths or 7.64 per cent. Since beginning the inoculations there had been in training at the hospital 113 nurses. Of these ten had had typhoid, one had had the vaccination and two had other sickness which made it inadvisable to proceed with the inoculations. Thus there were 100 eligible nurses and of these 76 per cent. have been inoculated. In the four classes the percentage of vaccinated nurses gradually rose from 61 per cent. in the first class to 100 per cent. in the last class. Since the work was started there had been no cases of typhoid among the nurses, but in the past there had been similar periods of similar length in which they were free from the disease. In addition to the nurses, vaccination was carried out on other people so that the present results were based on 150 cases. At the start only two doses of the vaccine were given, 400,000,000 and 600,000,000. This applied to only the first eighteen. After that the regular army dosage of 500,000,000 and 1,000,000,000, was given at ten days' intervals. Widal tests were taken on these cases at about ten days after the last inoculation in fifteen instances. In none was the Widal negative in dilutions of less than 1-100. In nearly all it was positive as high as 1-400, and in one case it was positive at 1-12,000. The reaction was done by the microscopic method. In seventy-two cases the effect on menstruation was especially noted. In 55 per cent. it was affected and in 45 per cent. it was not. In a fairly large proportion of those affected there was only a slight delay or a little earlier appearance of the flow in people who had previously shown no irregularity. In a few the reaction was more marked. Thus in one case the first menstruation succeeding the vaccination came on a week early and lasted for eight days, the next one lasted nineteen days. Then it resumed its regular course. One patient skipped two months. Given shortly before the time for the flow, the vaccine was quite apt to bring it on at once and to cause a severe reaction. There was no difference noted in the effect of different vaccine. Part of that used was kindly supplied to the hospital by Major Russell of the army. The rest were made at the hospital. Special attention was called to the fact that the vaccination should not be undertaken without going into the patient's history and assuring oneself that the patient was perfectly well at the time. For almost everything in the way of illness for some time after the inoculation was laid to the vaccine. Aside from this it was most important in view of the tendency to light up a chronic condition. In two of his cases it brought on attacks of tachycardia in patients who had previously had similar trouble. In one case a chronic appendicitis was apparently made more troublesome, requiring an operation after several months. In several cases tonsillitis developed a day or two after inoculation. The danger of lighting up a chronic quiescent tuberculosis, chronic joint trouble, chronic urethritis, etc., was well known. At the present time he was giving the vaccine in gradually increasing doses from 400,000,000 to 500,000,000 for the first dose, 700,000,000 to 800,000,000 for the second and 1,000,000,000 for the third. There was rather less reaction than when one gave the 1,000,000,000 for the second and third doses. It was also very satisfactory to follow the method of Spooner in Boston. He gave smaller doses at five-day intervals. With a limited experience with children he was of the impression that they rarely had any reaction to speak of.

**A Series of Cases of Staphylococcus Aureus Sepsis.**—Dr. Willard B. Soper presented this communication. The series consisted of forty cases collected from the records of Roosevelt Hospital, St. Luke's Hospital, and the Presbyterian Hospital. All showed the staphylococcus aureus and only the unquestionable cases were included in the report. There were twenty-nine deaths, eleven recoveries, and eight autopsies. In his summary of the lesions diagnosed clinically and at autopsy he gave the following: Osteomyelitis, 16 cases; pneumonia, 12 cases; suppurative arthritis, 10 cases; suppurative nephritis, 6 cases; cellulitis, 10 cases; carbuncle, 6 cases; abscess of the lungs, 5 cases; suppurative myocarditis, 4 cases; suppurative meningitis, 3 cases; splenic infarctions, 3 cases; parotiditis, 3 cases; acute vegetative endocarditis, 2 cases; thrombosis, 2 cases; brain abscess, 1 case; abscess of spleen, 2 cases; perinephritic abscess, 2 cases. With regard to the course of the disease, of the twenty-nine deaths 20 or 69 per cent. showed a duration of fifteen days or less. The recoveries required from six weeks to six months. With regard to the treatment of these cases of staphylococcus aureus sepsis there seemed to be a fulminant type which was the most common and in which any form of treatment was unavailing. With the other type of cases in which the infection was not so severe, the outcome would seem to depend on the ability of the surgeon to evacuate the pus from the seat of infection.

### Philadelphia Neurological Society.

At a stated meeting held October 25 Dr. Charles W. Burr presented a communication entitled "Paralysis Agitans in Negros," and he exhibited an illustrative case. He related that in his experience this was the first case of the disease in a negro that had come under his observation, and inquiry disclosed that this also was the experience of other physicians. The patient was a man, about 42 years old, whose preceding history could not be obtained. He presented characteristic fixity of countenance, marked festinating gait, with propulsion, slowness of movement, and partial flexion of the fingers, but with a total absence of the distinctive tremor. Dr. Burr pointed out that functional diseases of the nervous system are in general less common in negros than in whites.

Dr. Alfred Gordon reported "Two Cases of Myatonia Congenita" and he exhibited one of the patients. He pointed out that in some of the cases reported no changes were discovered in the nervous system, but only changes in the affected muscles, while in others chromatolysis of nerve-cells was present. The clinical picture comprises flaccid paralysis, more or less widely distributed, with quantitative reduction in electrical reactions, and without sensory changes. In the case of the colored child presented a positive Wassermann reaction was obtained, and intensive treatment with iodides resulted in marked ibprovement.

Dr. Francis X. Dercum exhibited "A Case of Hemiplegia with Unusual Symptoms." The patient was a man, 31 years old, who fell in walking on a gangplank from a boat to the landing, striking the back of his head. Thereafter he complained of some discomfort in the head, and a week later became unconscious. On returning to his senses the right side of the body was paralyzed and aphasia was present. In a short while the upper and lower extremities on the paralyzed side exhibited marked wasting, with abolition of the reflexes and preservation of sensibility.

Dr. N. Maxwell Langdon reported "A Case of Traumatic Bilateral Paralysis of the Facial Nerves, with Complete Loss of Power in the Upper Branches and But Little in the Lower." The patient was a man whose head was caught between the floor of a descending elevator and the landing. A fracture of the lower jaw resulted, and blood escaped from the nose, mouth, and ears, indicating a fracture at the base of the skull. The upper eyelids could not be depressed, the lower lids hung in folds, the forehead and brow could not be moved, and there was weakness in the lower part of the face. Hearing was impaired on both sides, as was also the sense of smell, and likewise the sense of taste on the anterior third of the tongue. The ocular muscles and movements were unaffected. There was a small area of anesthesia in the malar region on each side of the face. The conditions were attributed to injury of the affected nerves in connection with the fracture at the base of the skull.

Dr. T. H. Weisenburg exhibited a "Boy with Epilepsy in Whom There Occur Periodic Attacks of Hemiplegia." The patient was 16 years old and he gave a history of facial erysipelas at the age of four months. Subsequently, he had a number of attacks of epilepsy, and seizures have occurred since at long intervals, the last about two years ago. From time to time there occur attacks of transient hemiplegia involving one or the other side of the body, sometimes both sides, with exaggeration of reflexes, including extension of the great toe. The condition is supposed to be due to vascular derangement representing a form of intermittent cerebral claudication.

Drs. Chas. K. Mills and William B. Cadwalader presented a communication entitled "Pituitary and Unicigate Symptoms and Lesions," reporting a group of seven cases of this character, and demonstrating two of them. Of the latter one occurred in a man, about 35 years old, who had grown rapidly up to the age of 16 years and had put on a considerable layer of adipose tissue. The other occurred in a man, 30 years old, who was spare and pallid and rather short in stature, with a doubtful tuberculous lesion at the apex of one lung. Both complained of impairment of vision and examination disclosed the existence of bilateral temporal hemianopsia.

---

**Epilepsy in Infancy.**—L. Marchand calls attention to the occurrence during infancy of convulsions without any apparent cause, and without prodromi, which are not accompanied by any other morbid manifestations, and which do not seem to affect the general health. In these cases which are of an epileptic nature there are probably present cortical lesions which may have begun during intrauterine life.—*Gazette des Hopitaux.*

## Books Received.

*The* Medical Record *is pleased to receive all new publications which may be sent to it, and on acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Stuttering and Lisping. By E. W. Scripture, Ph.D., M.D. 251 pages; illustrated; cloth; price $1.50 net. The Macmillan Company, Publishers, New York.

Life: Its Nature, Origin and Maintenance. By E. A. Schäfer, LL.D., D.Sc., M.D., F.R.S. 36 pages; cloth; price 50c. net. Longmans, Green & Co., Publishers, New York.

Diseases of the Liver, Gall-Bladder and Bile-Ducts. By Humphry Davy Rolleston, M.A., M.D., F.R.C.P. 811 pages; illustrated; cloth; price $9.00 net. The Macmillan Company, Publishers, New York.

## Therapeutic Hints.

**Subcutaneous Injections of Sodium Iodide.**—M. J.-L. Champion states that a small dose of sodium iodide injected into the cellular or muscular tissue is quickly absorbed and does not cause any pain. It produces certain interesting therapeutic effects, acting both as a sedative and as an antispasmodic. The author injects 0.02 gram of the drug dissolved in 2 c.c. of water, sterilization being effected by heat. The salt used should be pure and desiccated; the crystalline salt is apt to irritate. Good results have followed the local use of this drug in intercostal neuralgia, sciatica, lumbago, headaches, the pleurodynia of pneumonia, the pain associated with abscess formation, and in iritis and phlebitis. The administration of this drug is indicated as a primary measure in rheumatism. The author has also demonstrated its value in vertigo, in various forms of dyspnea, in edema of the lung, and in angina pectoris. The action of the drug in all of these cases either is immediate or may be delayed for several hours. Sodium iodide is a vasodilator and to this must be attributed its analgesic and antispasmodic actions.—*La Presse Médicale.*

**Therapeutic Value of Colloidal Rhodium.**—Pechère has obtained good results from the use of colloidal rhodium in various infectious processes in children. This drug was resorted to because of the minuteness of its particles. It was injected intravenously when possible, or, in the case of young children, intramuscularly, in doses of one-half a cubic centimeter, containing .2 milligram of the drug. The chief action of the drug was to cause a fall in the temperature.—*La Policlinique.*

**Formalin in the Treatment of Tuberculosis of the Upper Air Passages.**—H. Bourgeois has employed in this condition the mixture recommended by Morestin. It consists of equal parts of formalin, glycerin, and alcohol. A few drops of this mixture are injected into the tuberculous granulations. This method of treatment is also of value in the cauterization of the granulations of chronic otitis media.—*Progrès Médical.*

**Treatment of Subacute Bronchitis.**—Grasset recommends the following to be administered in pill form, four or five times a day:

℞ Codeine, 0.01 gram.
Terpene hydrate, 0.20 gram.
—*Gazette des Hôpitaux.*

**Postanesthetic Vomiting.**—E. Chauvin and N. Æconomos find that the administration of the following potion serves to prevent the onset of postanesthetic vomiting:

℞ Glucose, 150 grams.
Tincture of nux vomica, 0.50 c.c.
Tincture of canella, 3 c.c.
Water, sufficient to make 300 c.c.
—*La Presse Médicale.*

**Treatment of Diarrhea.**—E. Fuld believes that many cases of diarrhea are to be attributed to an increased irritability of the stomach. The contact of food with the gastric mucosa reflexly excites intestinal peristalsis. He recommends for the purpose of diminishing this excessive irritability of the gastric mucosa the following mixture:

℞ Cocaine hydrochloride,
Codeine Phosphate, of each, 3 grams.
Peppermint water, 100 c.c.

Of this solution the dose for adults is 10 drops ten minutes before meals.—*La Semaine Médicale.*

## Miscellany.

**Doctor Johnson and the Doctors.**—"Dr. Johnson," says Boswell, writing under date 1784, the year of Johnson's death, "had in general a peculiar pleasure in the company of physicians," and this was certainly not abated when he took tea at Oxford in the company of Dr. Wall, a "learned, ingenious, and pleasing gentleman." It was on this occasion that the great moralist prophesied, in some sort, the necessity for research into the diseases of the East and of warm climates. He fell foul of the Radcliffe Traveling Fellowship, and averred that the Fellows had done very little good. "I know nothing that has been imported by them; yet many additions to our medical knowledge might be got in foreign countries." And he cited inoculation as having saved more lives than war destroys, and the unnumbered cures performed by Peruvian bark. "I would send the Radcliffe Fellows," he cried, "out of Christendom; I'd send them among barbarous nations." Johnson's kindness to poor old Dr. Robert Levett, his pensioner, is, of course, famous, and equally so are the lines he wrote on the doctor's death at the age of 80 in 1782. Goldsmith, also a physician, was among his intimates, and the chaff bestowed on his new plum-colored coat has become immortal. The coat, terribly worn and threadbare, is now in the London Museum, and suggests the pathetic supposition that the spendthrift poet-physician wore it till it was almost unpresentable. At the time of Goldsmith's death in 1774 Johnson wrote, "Of poor dear Dr. Goldsmith there is little to be told." Goldsmith probably owed £2,000, not less, and this preyed on his mind and heightened a fever, which he further complicated by an excessive use of James' powders. Referring to the debt Johnson humorously asks: "Was ever poet so trusted before?" Later, writing to Bennet Langton, he says, "Let not his frailties be remembered; he was a very great man." If Goldsmith by his over-medication hastened his own death, Johnson by dint of amateur surgery did likewise. Shortly before his death he inflicted such wounds upon himself, in the hope of obtaining relief, as to suggest the idea of suicide. He used a pair of scissors in an endeavor to void the water of dropsy. Johnson's last words were many. To the faithful Langton he said tenderly: "Te teneam moriens deficiente manu." Of his man nurse he said, with a flash of the old humor: "Sir, the fellow's an idiot; he's as awkward as a turnspit when first put into the wheel, and as sleepy as a dormouse." His last recorded words were to a young lady who had asked for his blessing: "God bless you, my dear."—*Lancet*, December 21, 1912.

**The Daily Routine of Ambrose Paré.**—J. G. Mumford says Paré "rose at four in the morning and went at once to his surgery, where he read and wrote until six; then he breakfasted on milk and dry bread. At six-thirty he began the reception of patients, who thronged to him until eleven o'clock, when he dined. After dinner he slept for a half hour, when he started forth on his rounds, on foot or horseback—surgeons had no carriages in those days. Often he visited the Hôtel Dieu, where he operated and taught and where he wrote over the door: 'I dress the wound; God heals it.' He supped wherever chance found him—in some humble shop, at the hospital, the Louvre, rarely with his wife at home; then to his studies again, or to see more patients, and at last to bed, at midnight or long after." —"A Doctor's Table Talk."

### SOME PROBLEMS OF NURSING: A PLEA FOR GRADING.*

By HENRY DWIGHT CHAPIN, M.D.,

NEW YORK.

One of the greatest advances made in the successful treatment of the sick and injured was accomplished when the regular instruction and training of high grade nurses was inaugurated by the hospitals as part of their regular service to the profession and to the public. Probably very few in actual practise to-day realize the full benefits of this movement as they have had no experience of what preceded it. Too often, the records tell us, the nursing of the sick was relegated to ignorant, slovenly, and haphazard women who were more noted for loquacity and assurance than for skill. When these failed or could not be procured, the members of the family were obliged to lend a hand although fatigued and worried by lack of experience in attempting to minister to those near and dear to them. They were also without a certain authority to carry out necessary measures that often are best undertaken by an outsider. By inaugurating a new, useful and dignified profession, which could fill the needed gap between physician and patient, the required advance was accomplished.

Sufficient time has now elapsed in this beneficent movement to inquire if it has attained its widest usefulness, and, if not, how the work of the hospitals may be broadened out to reach a wider social service than has yet been attempted. The writer believes this can be done by a differentiation or grading of nurses, as every practising physician knows that a wide field has never been properly covered by the nursing profession as now in operation. The reason for this is obvious—lack of means.

While the advances in modern, scientific medicine have been prodigious, the necessary expenses attending such service to the sick have likewise increased, but the incomes of the masses have not correspondingly advanced. Great hardship has followed to many worthy people. Physicians are constantly seeing severe cases of illness inadequately nursed owing to lack of money.

With the increase of expense due to necessary scientific examinations and laboratory tests, the nursing has likewise increased in elaboration and costliness. This is satisfactory enough in a well-equipped hospital, but what of the homes of even relative or comparative poverty? It sometimes seems as if the millionaire or the pauper were the only ones to be assured of modern, scientific treatment. This is a grave condition for many practising physicians to meet.

*Read before the New York Academy of Medicine, Dec. 19, 1912.

On the nursing side, the trained nurse has practically the field to herself. Fortunately for the public, she has driven out the old-fashioned nurse and no one has regularly taken the place of the latter. It is now frequently a trained nurse or nothing. In the face of this problem, the training of the regular nurses has been elaborated, the time of study and service enlarged, and the cost of their services correspondingly increased. It seems to be the popular cry at present to raise the standard in everything. We may well inquire whether this is always an unmixed blessing. As far as nursing is concerned, I would both raise and lower the standards. This would involve a change in some of the methods of training in order to make the output of the schools more varied and elastic and thus more responsive to every day public needs.

As at present constituted, some of the instruction given to the average nurse is needless and much hard labor is exacted that is not particularly valuable as far as training is concerned. We neither want semi-doctors nor mere drudges to depend on in average nursing. It seems to me that the best solution of this question, both for the nurses and the varying public they must serve, is to establish three distinct grades of students at the training schools. Let some of the student nurses be trained as broadly and highly as possible, but widen the field and usefulness of the training schools by introducing lower grades.

As a tentative proposition, let us divide the students into three classes, included in Grades I, II, III.

*Grade I.*—This should consist of well educated, cultured women, with a course of at least three years before graduation. In the absence of a college degree, or equivalent education, a preliminary and thorough examination should prove their fitness for advanced instruction. While practical training should not be neglected, much of the ordinary drudge work could well be omitted. While the idea of making pseudo-doctors is not desirable, they should be thoroughly instructed in the elements of anatomy, physiology, and the natural history of diseases. This would enable them to become expert in waching, and, to a certain extent, interpreting the significance of symptoms as they may arise at the bedside. Here is where many nurses fail. Even if a proper attempt has been made to teach them these things in the training school, they are physically and mentally too tired to grasp and remember them after a long, hard day of work in the wards. By saving this grade from much of the routine drudgery, their minds would retain the necessary knowledge. A careful instruction in history taking and recording—and in good, crisp, legible English—need not be neglected. A thorough course in hygiene and the ideas and methods of preventive medicine could likewise be included in the course. Domestic economics and scientific housekeeping, on

a large and small scale, should be thoroughly taught to this class. The nutritive value, varied utility, and, to a certain extent, the chemistry of foods, would be highly desirable. This would also include the purchase and proper preservation of foods in large or small quantities, fit either for the home or institution. Proper tests for recognizing pure, unadulterated food stuffs and scientific cooking in all its branches would be included in the course of instruction.

The economics of institutional work in its varying phases should also be carefully studied. Such a training would enable one to preside over the complicated routine of an institution, oversee a social settlement, or nurse the most complicated and difficult case in a private family. The social poise developed by such an education would be at home alike in the most elaborate mansion or in the more restricted surroundings of those in poorer circumstances who occasionally need such services. It is usually the most cultivated who can readily adapt themselves to diverse surroundings.

A rigid examination should be successfully passed before the candidate would be given the diploma of this highest grade. A distinct dress and badge might be the outward sign of having attained the grade. If a student cannot pass the necessary tests, both as to character and attainments, she could be dropped to the next lower grade where the requirements would not be so severe. A special title could also be given, perhaps some such title as Registered Special Nurse might do.

*Grade II.* The requirements for entering this grade would be an average education such as is reached in the ordinary high school. The time of study would be two years, but in the last few months of the course the pupil nurse would be sent out on private cases in order to become familiar with the conditions of household nursing. This was formerly done in some of the training schools and had a distinct educative and helpful value. Hospital nursing and that done in the home, often with restricted appliances, may be very different in character. Some nurses, who do very well in the hospital, fail to make as great a success in private practice, and more effort should be made to teach them to adopt themselves to the varying circumstances they are sure to meet in practise. A certain tact and sense in dealing with human nature under diverse and frequently trying conditions are essential to success.

While the theory and practise of nursing should be adequately covered, the course need not be so rigid as in Grade I. Some of the repeated manual work now required could be omitted and this would give more time and strength for the skilful exercise of their powers. Both of the upper grades of nurses should be instructed in the elementary teachings of bacteriology so as to fit them to understand and apply the principles of sepsis and antisepsis, especially as related to surgical operations and dressings. An examination should be required before graduation to see that the candidate understands the principles that have been taught, but the record of work actually done in the wards should count very largely in the final estimate. Upon graduation the usual title of Trained Nurse would be employed and she would occupy the field now given over to this class.

*Grade III.* Here is where a more radical change is advised. It will aim to open up a broad and necessary field that will, on one side, give employment to a large class of worthy women, and, on the other, supply an equally large class who need their services. We hear much of small wages, uncertain work and hard conditions of labor on the part of working women. Let us open a new field of opportunity to this class by training large numbers of them to be practical nurses. These women could be sure of useful work at a moderate wage, but larger than the shops and factories can offer. A very large number of cases of illness require nothing more than this class could easily furnish if they had a little discipline and training. Such a course can best be given by taking part in the practical, routine work of a hospital for a comparatively short time.

A candidate should be strong physically and have a simple education, such as is given in the ordinary grammar grades in our public schools. While doing a fair share of the drudgery of the ward, she can still assist and see the necessary manipulations required in actually handling the sick and injured. One year of such service and instruction in the wards of a well-regulated hospital would turn out nurses capable of taking care of a great majority of the ordinary cases of illness that are met in actual practise. They would be vastly superior to the output of the various haphazard methods of supplying a certain kind of nurses. They would also be valuable in many cases where second nurses or assistants are required in difficult cases. They could be called Trained Attendants, but they would be very different from the class now generally known by that name. The latter have usually attended a few lectures, but have had no regular, systematic hospital training. This is a grade that needs enlarging and developing so as to fill a wide and useful field. At present not only have most of them had inadequate training, but they are subject to no proper oversight. If they were recognized as an integral part of the hospital trainng, they would have a regular status on graduation. By registration, with some oversight, they would then take their place in the same way as the graduates of the higher grades with a consequent professional standing and responsibility.

There will doubtless be objections in trying a combination in one school of women possessing a different standing and education. Each grade, however, could have separate quarters and need not mingle if they do not so desire. The true dignity and value of their work should be impressed upon all the grades—each feeling that they are in preparation for a career that, in spite of its limitations, cannot well be excelled in usefulness if it is entered into with the proper spirit.

The plea of this paper is to so broaden out the field of instruction in nursing as to reach all classes equally and adequately, and not simply have a profession that, as now organized, can really only serve the well-to-do. The superintendent who can practically carry out such an ideal will deserve to stand with Florence Nightingale as a benefactor of the race.

Thoughtful statesmen and publicists all over the world are trying to study out and remedy the high cost of living to those upon whom it bears hardest. Let physicians and nurses lend a hand in trying to reduce the high cost of sickness to those who can least afford to suffer under such misfortune.

51 West Fifty-first Street.

# RADIUM AND THORIUM-X THERAPY.*

By DR. CARL VON NOORDEN,

DIRECTOR OF THE FIRST MEDICAL CLINIC IN VIENNA.

The discovery of the radioactive elements and their properties has overturned the views of the structure of matter, which we have held for more than one hundred years. New forces have been discovered which slumber in the molecules and are given off outwardly according to definite laws. Hardly had science established the most important facts than we learned that the newly discovered forces also influence biologic processes. Naturally it was not long—perhaps we should say in retrospect all too short—before therapeutics sought to avail itself of the new forces.

*Physics.*—The most important chemicophysical property of radioactive elements is that while giving off a so-called radiation they are disintegrated into new elements with smaller atomic weights. Thus far we have become acquainted with three kinds of rays, which differ among themselves completely in their nature. The so-called Alpha-rays are helium atoms charged with positive electricity. The so-called Beta-rays are electrons, that is, the smallest units of negative electricity. The so-called Gamma-rays are not material particles. We interpret them as an electromagnetic vibration in the ether, related to light. They cannot be shown to carry an electric charge.

The three kinds of rays are given off from the individual radioactive substances in different admixture, but from each individual substance in entire accordance with fundamental laws. Of great significance is the velocity with which the disintegration takes place. As a measurement for them there has been chosen the so-called half "value interval," that is, the time which elapses until a certain quantity of a radioactive body, while giving off the characteristic radiation, has been transformed half way into the next following element. These intervals vary greatly, and on that account important viewpoints for therapeutic applicability of the individual preparations result.

I will not go into details about the half value intervals. The size of the single values is to be seen from two accompanying tables. The products of the uranium-radium series and those of the thorium series are conspicuously enumerated. I will return to these tables later, as certain figures therein have practical significance for the physician.

TABLE OF HALF VALUE INTERVALS.

URANIUM-RADIUM SERIES

| *Element* | *Rays* | *Half-lifetime* |
|---|---|---|
| Uranium | $\alpha$ | 5,500 million years |
| Uran-X | $\beta$-$\gamma$ | 24.6 days |
| Uran-Y | $\beta$ | 1.5 days |
| Tonium | $\alpha$ | 200,000 years |
| Radium | $\alpha$, $\beta$ | 1,760 years |
| Radium-Emanation | $\alpha$ | 3.85 days |
| Radium A | $\alpha$ | 3.0 minutes |
| Radium B | $\beta$, $\gamma$ | 26.2 minutes |
| Radium C | $\alpha$, $\beta$, $\gamma$ | 19.5 minutes |
| Radium D | $\beta$ | 16.5 years |
| Radium E | $\beta$ | 5 days |
| Radium F (=Potassium) | $\alpha$ | 136 days |
| Lead (?) | | |

THORIUM SERIES

| *Element* | *Rays* | *Half-lifetime* |
|---|---|---|
| Thorium | $\alpha$ | 1,000 million years |
| Mesothorium 1 | (?) | 5.5 years |
| Mesothorium 2 | $\beta$, $\gamma$ | 6.2 hours |
| Radiothor | $\alpha$ | 2 years |
| Thorium-X | $\alpha$, $\beta$ | 3.65 days |
| Emanation | $\alpha$ | 53 seconds |
| Thorium A | $\alpha$ | 0.14 seconds |
| Thorium B | $\beta$ | 10.6 hours |
| Thorium C | $\alpha$, $\beta$ | 60.5 minutes |
| Thorium D | $\beta$, $\gamma$ | 3.1 minutes |

*Read before the New York Academy of Medicine, October 29, 1912.

The radioactive bodies are, as already said, carriers of energy. That which we make use of biologically is living force set free in the instant of disintegration. It is expressed in development of heat, in electricity, in chemical transformations. For example, water is decomposed by the Alpha-rays and the oxygen of the air is ozonized. In order to give an idea of the amount of energy generated let it be mentioned that one c.cm. oxyhydrogen-gas develops on explosion two gramcalories. One c.cm. of radium emanation in its complete disintegration develops, on the other hand, about twenty millions of calories, that is, about ten million times as much. By far the greatest amount of the total energy accompanies the Alpha-ray. The manifold action of radioactive substances upon the organism depends upon that development of energy. The radioactive substances act while they disintegrate, or, one may perhaps say, in the instant of their explosion; for the process which takes place in the individual molecule of radioactive substance is in fact an explosive one. This consideration causes us to reflect upon what happens when we introduce a radioactive substance into the body and when this substance is distributed by means of the blood in all the tissues and cells. We permeate the body with molecules which have a tendency, after a certain time, determined by their peculiar nature, to explode. They hurl thereby, in their immediate environment, an amount of energy gigantic in proportion to their mass. Like the water molecule, other inorganic and organic molecules and cell constituents may be dissociated and it should not cause wonder that many vital expressions of the cells become thereby essentially modified. Until now we have only quite imperfect knowledge of the alterations of the biochemical processes which are accomplished under the influence of radiant energy. The affinity of individual tissues and tissue cells for radioactive substances is certainly not everywhere the same; just as alkaloids, metals and metalloids, immune bodies, etc., anchor themselves by preference to definite cell groups and with definite chemical substances of the body, while other cells do not take them up. We have already attempted to demonstrate such an elective anchoring of radioactive substances in the body. The results thus far are, however, not definite. For the time we may only derive the elective anchoring through analogies which will explain to us why radioactive substances seem to work much more strongly on certain organs than on others. The most powerful force which becomes active through the explosions of radioactive molecules is electricity. Thus, now, radioactive substances give us a method of distributing the carriers of electrical energy into the interior of the body and there engage the fluids, the protoplasm, and the cell nuclei in the immediate bombardment of electrical atom explosions. We can therefore designate internal therapy with radioactive substances as an internal electrotherapy.

*Methods of Application and Their Value.*—After these prefatory remarks on physics, we must first occupy ourselves with the practical applicability of the various radioactive substances. I remark that in the following paragraphs I will only go into such questions and points as are important for internal medicine. The application of radium in dermatology

and surgery I will not consider, for I have had no personal experience here.

Hitherto few among the radioactive substances have attained importance for internal use. We must demand from a utilizable preparation:

1. It must be agreeable in its application, that is, without hardship to the patient. Properly dosed it should have no injurious collateral action.

2. The velocity of disintegration should not transgress certain superior and inferior limits. Such substances show themselves most utilizable whose half value intervals amount to several days. This applies only to radium emanation and thorium-X.

3. Irrespective of what substance we choose, we must be sure of the dosage. We must know exactly how much energy we allow to act on the body. In this regard many justified complaints have become current; for the preparations to be found on the market and which are accessible to physicians, are in part dosed very inaccurately. We measure the acting force of the preparations according to electrostatic units. Since, however, the use of electrostatic units gives too small figures, the number found is, as a rule, multiplied by 1,000; one obtains then the so-called Mache-unit. One thousand Mache-units make one electrostatic unit.

4. The preparation should be reasonable in price. That for the time being, intolerable conditions still prevail on the radium market, appears from a work carried out by G. Mossler, at the request of the Austrian government. He found truly fabulous differences in price for the same amount of energy. For example, in seven different bath preparations the price per each 1,000 Maché units varied from about 2½ cents up to about $125. In the potable preparations and in the radium compresses, the differences in price are smaller, but still very considerable. Many bath preparations are so dear that it would be cheaper to take a full bath in French champagne than to arrange a bath by these preparations, which would have perhaps half the strength of a Gastein bath. With the cheapest preparations, on the other hand, one attains the full strength of a Gastein bath for about $1.

Under the pre-supposition of careful and conscientious preparation the following radioactive substances have thus far proved themselves the best: A. Radium emanation. B. Radium and its salts, partly in solid form, partly in solutions. C. Solutions of Thorium-X.

### RADIUM EMANATION.

Emanation is a gas which follows all the laws of gases. Two gases proceed therefore from metallic radium and its salts: the now constant helium and the spontaneously disintegrating emanation. As especially noteworthy it is to be mentioned that by further disintegration emanation is changed back again into a solid substance. Under a continuous radiation are formed from emanation in rapid sequence, one after another, a series of solid bodies, to which one has given the names radium A, B, C, and D, and which are endowed with the collective name of "active precipitate." In radium D we encounter a substance, which disintegrates very slowly. Radium D seems to be somewhat indifferent for the organism.

*Baths.*—Emanation is by far the oldest form for therapeutic application of radioactive substance. Long before we knew anything of the existence of radioactive elements, we utilized for medicinal purposes baths, that are rich in emanation and we hailed their therapeutic accomplishments without knowing upon what they rested. I give here a tabular survey of a few springs, whose healing power, celebrated of old, we must bring at least partly in connection with their emanation content.

A full bath (200 liters) contains of Maché units:

| | | | |
|---|---|---|---|
| Landeck (Tirol) | ca. 40,000 | Münster a. Stein | 4,680 |
| Gastein | ca. 30,000 | Pistyan | 4,680 |
| Baden-Baden | 25,000 | Kudowa | 4,500 |
| Kreuznach | 11,200 | Soden im Taumus | 4,400 |
| Nauheim | 5,720 | Nenndorf | 4,000 |

To these must be added the extremely strong baths of Joachimsthal in Bohemia. The "Radium-Kurhaus," that place fitted out with all the accessories of modern technique, guarantees a content of 120,000 Maché units in a full bath.

When Neusser by introduction of pitchblend residues in a common bath gave to this the strength of a Gastein Grabenbäcker Spring Bath (about 30,000 M.U.) and saw therefrom a favorable influence upon chronic rheumatic processes, he had taken the first step in the application of artificial radioactive baths and especially to the intentional application of radioactivity in internal medicine. The residues which remain in the manufacture of uranium colors contain a mixture of all the radioactive substances in the uranium series; that which is given off in the leaching water is essentially emanation. When in Joachimsthal the abundantly present residues are leached in closed tanks, one may obtain surely inexhaustible quantities of bath water probably still more strongly saturated with emanation than the water now in use, as the so-called "residues" are much richer in radium than the original ore. One will adopt this simple and cheap process when the subterranean water which flushes the uranium ores no longer suffices to cover the rapidly increasing demand.

It has been disputed that in the use of bath, rich in emanation, any notable amount of the latter or its radiation reaches the interior of the body. It has been said the skin refuses entrance to the gas and but few of the rays penetrate it; only the gas which, according to the well known laws of gases, diffuses from the water into the air above and is then inhaled, exerts any action. According to more recent investigations, however, the emanation seems to penetrate the skin better than was at first thought. Nevertheless, in Joachimsthal they have arranged by the erection of specially high tubs, that the heavy emanation gas more fully remains in the respiratory air of the bather.

We must come to an agreement as to which baths shall rightly be recognized as radium baths. I believe that we should recognize certain groups as follows: (1) Strongly radioactive springs—100 M.U. and upwards in one liter of water; (2) Radioactive springs of medium strength—50 to 100 M.U.; (3) Weakly radioactive springs—20 to 50 M.U.

Where the emanation content of the water is still smaller than 20 M. U. in a liter, one should no longer term it a radioactive spring. Nevertheless it should be mentioned that individual health resorts, for example, Teplitz-Schönau, have ingeniously succeeded by the aid of their weakly radioactive water (maximum 8.7 M.U. per liter) in reinforcing strongly their inhalation chambers with emanation.

*Inhalation* represents the second form of application of emanation. The principle is very simple. In a closed space the walls of which are made as

air-tight as possible, is distributed the emanation. A ventilator assures the uniformity of the distribution. The air is obtained in a respirable form through the introduction of oxygen (from bombs of compressed oxygen).

Carbonic acid and aqueous vapor are removed by special absorption apparatus. As a very suitable one and capable of manifold application, I must designate also the portable emanation chamber. This is a tent of rubber cloth, which can be set up in a few minutes over any bed, and prevents the entrance of the external air. We have often allowed patients with severe joint troubles, who could not be transported, to inhale thus for many hours in succession, and believe we have to attribute much success to this continuous action.

The treatment in the emanatorium had its beginning, as is well known, in Berlin, founded on the experiments which were carried out in His's clinic. Now there are emanatoria in all large cities, in all health resorts, and in most of the smaller cities; but some of these deserve the reproach that their inhalation chambers are provided with much too small amounts of emanation, and that the results depend more upon the suggestive influence of the chamber than on the content of emanation. Nevertheless I must agree with His and his pupils that in single, specially sensitive individuals—especially in subacute articular rheumatism—typical reactions are obtained with air-mixtures of from 4 to 8 M.U. per liter, and that it is unsuitable then to apply stronger mixtures. These, however, are only exceptions, and I believe that, by reason of our very extensive experiences, I may say in advance, that about 25 M.U. per liter is the least amount required for which an actual practicable emanatorium should be arranged. We ourselves did not stop short at this quantity. In the preceding year I published in common with my assistant, Dr. W. Falta, a communication in which we reported on the application of very large amounts of emanation. At that time the maximum was 675 M.U. in a liter. In the meantime we have gone as high as 1,200 M.U. This happened, however, only while studying the influence of very large doses. I think that for therapeutical purposes one does not need to exceed 500 M.U. per liter.

When the physician refers a patient to an emanatorium he should know exactly what the dosage of the latter is. Therefore we should, just as in the case of the baths, unite upon a certain conventional gauge for the emanatoria. The following scale seems appropriate to me: Weak emanatoria: 8-12 M.U. guaranteed per liter of air; medium, 12-25 units per liter; strong, more than 25 units per liter.

Inhalation chambers which guarantee less than 8 M.U. in a liter of air, should not possess the right to call themselves emanatoria.

At present the great expense stands in the way of the erection of powerful emanatoria; aside from a few, which are subsidized by the State, really powerful emanatoria do not yet exist. My clinic belongs to those fitted out through State aid. It may be of interest to mention that the market value of the emanation used by us per diem reckoned at its lowest price amounts to $100 to $200.

By far the greater part of the emanatoria in operation maintain themselves at the lower limit. As far as I know only in the Joachimsthal Radium Kurhaus are the average charges up to the superior limit of the first category, and in the future, through the projected improvements, these can be strengthened to perhaps 15 to 20 M.U. a liter of air without essentially adding to the expense. There, however, the conditions for obtaining cheap emanation are specially favorable.

Of the weak emanatoria it is objected that for the high charge but little emanation is incorporated and brought into action. In fact the quantity is not large and the action is limited to the time of the sojourn of the patient in the chamber. Already after a few quarter-hours the last of the emanation has been given off, principally through the expired air, and further, the entire amount of the so-called "active precipitate" formed meanwhile in the body has gone over into nearly inactive radium D. It is also held against the emanatoria that it is not advisable to shut in the patient for several hours a day in the relatively narrow space, in which indeed he is well taken care of as far as the introduction of oxygen and absorption of carbonic acid go, but by prolonged use an essential deterioration of the air is unavoidable in these chambers. These are important objections and we therefore welcome the already constructed portable apparatuses suitable for individual use. Nevertheless the system of all these apparatuses is still very susceptible of improvement. I believe we shall soon see the construction of such relatively cheap emanation inhaling apparatuses in great perfection. One will then be able to supply a mixture of any desired strength, beginning with small doses and gradually rising to larger ones.

*Drinking.*—The third form of application of emanation is the drinking cure. This mode of application is especially suitable when one wishes to act upon the stomach, intestine, or liver. I would like to mention here that we have obtained by means of the drinking cure some excellent results in abnormal irritable states of the stomach, in simple hyperesthesia of the stomach, in hiccough, in morning vomiting, and hyperemesis. Daily doses 1,000 to 2,000 M.U. served as a rule. That is indeed very little in view of the rapid elimination of the emanation. The total action must be notably smaller than that even of the weakest emanatoria. We have used as a rule, for the daily dose, 20,000 M.U. and often very much more, and I believe I must credit to these large doses the fact that my final judgment of the drink cure is strongly favorable.

*Compresses.*—The action of the so-called "radium compresses" is to be referred partly to emanation, partly to direct radiation. One uses them especially in subacute and chronic rheumatic arthritis, also in neuralgia. From the moistened compresses some emanation doubtless penetrates the skin, and enters the neighboring tissues and general circulation. Radioactive pillows, compresses, etc., which give out really abundant emanation, are so extremely dear that they are applicable only to the smallest extent. We obtained such strongly acting pillows for experimental purposes, which the Neu-Lengbacher Radium Works placed at our disposal; and I also saw such pillows in use at the Joachimsthal Radium Sanatorium. The results appeared to me very satisfactory. When one does not have at one's disposal specially strong preparations of radium the application of a radium bag as well as that of the radium metal and of the undissolved salts should be limited essentially to those cases where the action is meant for the most superficial layers. This is of interest rather for dermatology and surgery than for internal medicine.

*Subcutaneous Injections of Radium Salts.*—Emanation is used only exceptionally for injection. The action in this form of application is too transitory. On the other hand the injection of weak radium solutions (bromide or chloride) belongs to the earlier forms of application, and recently, as it seems to me with right, has gained new ground. Radium itself is eliminated but slowly. We establish by repeated injection, in a measured interval of time, a radium deposit in the body from which continually emanation and electric energy are given off. As a rule one applies phials of one c.cm. capacity, which contain enough radium in aqueous solution to provide an emanation which, in radioactive equilibrium, corresponds to a value of 1,000 M.U., that is 1/6000 mgr. of radium metal (0.00017 mgr.). According to our own experience it does not appear very intelligible that with such minimal quantities therapeutic activity is obtainable. We believe that even for the acquisition of local action manyfold the above mentioned dose must be injected. Local action comes especially in question in chronic rheumatic affections of the joints. One injects the radium solution in the vicinity of the joint. But if one will obtain general action, if one will make use of the strong influence of radium injections upon the erythrocytes and leucocytes very large doses are required. My assistant, Dr. Falta, who with tireless industry most laboriously studied the action of radium in my clinic, found (in common with O. Brill, E. Freund, and L. Zehner) that in animals the action upon the composition of the blood only begins when in a single dose about 1/200 to 1/100 mgr. of radium is injected per kilo of body weight. Disturbing collateral action which could make the injections dangerous was not seen. For a body weight reckoned at 70 kilos the amount of radium used would therefore amount to from 1/3 to 2/3 of a mgr. With such very large doses no experiments have yet been made. More accurate statements as to the actual indication for radium injection and the size of the appropriate dose are needed. We are still in the experimental stage. In any case one must go far beyond the extremely minute doses with which we were first contented. We also need a much better guarantee than before that in the purchasable ampullæ as much radium is really contained as is claimed. As a whole, I believe that the prospects of radium injection therapy are very great, though it would be premature to assert that these injections are of extreme therapeutic efficacy, and just as much so, and this has already happened—to make of them a new therapeutic specialty. This can lead to only wrong paths.

THORIUM.

In the thorium series we also find a gas, thorium-emanation, which is interposed in a long series of elements of the solid state of aggregation. Thorium-emanation is, however, not useful for our purposes. It disintegrates too rapidly. It disintegrates more rapidly than one can breathe it in, in the radiation and in the nonvolatile active precipitate.

Of the other bodies of the thorium series *mesothorium-2* was the first to be selected. One used it for injections, but mesothorium-2 has also the disadvantage of an all too brief duration, and to obtain it in pure form and to use it also presents certain technical difficulties; further, as soon as it is decomposed an element is formed therefrom (radiothorium) which, on account of its very slow disintegration, must be designated as indifferent.

Medical interest has rightfully been applied almost exclusively to thorium-X. This is a solid substance with a half value interval of 87.5 hours. It belongs chemically to the alkaline earths, forming salts which are easily soluble. Itself very rich in rays, it has elements in its train which all decompose pretty rapidly. Thorium-X is eliminated only very slowly, so that a large portion—perhaps the greater part of the injected molecule—undergoes all its phases in the body itself, until there is reached a last product which is no longer radioactive, and the nature of which is for the time being still unknown. There are, therefore, at least five electrical explosions of every individual thorium-X molecule accomplished in the body. The great utilization of the individual molecule and the fact that it can be precisely dosed, make thorium-X a very strong competitor of radium emanation, in which the dosage is always somewhat uncertain, and at best controllable only with extreme difficulty. From what has been known hitherto, the biochemical activities of the radium series and the thorium series are of the same quality. Solutions of thorium-X have been used by subcutaneous injection, and also as drink cures. In principle both appear to be equivalent; the results are practically the same, what differences there are being comparable to those observed in giving morphine subcutaneously or by the mouth. One must learn which mode of application is most advantageous under the existing circumstance.

In administration by the mouth we have seen, when large doses were frequently repeated (from 300,000 to 500,000 M. U.), slight gastrointestinal disturbances, especially loss of appetite and slight nausea, but no other disadvantageous consequences. Drink cures with smaller doses, say 50,000 to 100,000 M. U. are, doubtless, well borne by the digestive canal. Some prefer the intravenous injection to the subcutaneous. There does not seem to be any noticeable difference. As appears from the communications from my clinic there is, after subcutaneous injections for the next four days, only about 28 per cent. of the injected amount of thorium excreted by the feces and urine. The greater part therefore remains up to the complete cessation of radioactivity within the body. It is interesting that thorium, as well as the common alkalin earths, is eliminated for the most part by the bowel and for much the lesser part by the kidney.

As will be remembered, the first clinically important communications upon the therapeutic applicability of thorium-X were published at exactly the same time and independently of each other from my clinic and from that of F. Kraus by W. Falta and Plesch respectively. They found valuable and instructive supplement in the simultaneous investigations of A. Bickel in animal experiments. The enormous sensitiveness of the bood, as well as of the blood-forming apparatus toward medium and even small doses of thorium-X promptly appeared. This holds for the leucocyte as well as for the erythrocyte system. The discovery led naturally forthwith to therapeutic researches in leukemia and in pernicious anemia. The communications concerning the experiments and results made to this year's Congress of Internal Medicine caused a justifiable sensation. They exceeded all hitherto known of the action of radioactive substances on the blood. Even the strongest radium injections previously applied were far behind, and still greater was the difference in comparison with the action

of radium emanation. Unfortunately in the beginning the forces and energy, innate in thorium-X, were underestimated. In the more daring procedures a fatality occurred. The unfavorable termination was caused by severe hemorrhagic diathesis. This very lamentable accident warns us certainly to caution, but we should not be frightened away from further completion of thorium-X therapy. In a very large number of injections we have had, in my clinic, no ill results and also the more recent communications of A. Bickel, H. Hirschfeld, and G. Klemperer—which only confirm those from my clinic and that of Kraus' as reported to the Wiesbaden Congress and support them with new examples—there is nothing which could frighten us from further testing thorium-X. Naturally it is a two-edged sword like any poison. It is only a practicable and profitable weapon when it is *correctly* dosed. The time seems to me not yet arrived, when we can recommend thorium-X for general practice. We are in the experimental stage with it even more than with the radium emanation therapy. The emanation therapy suffered because in the beginning the doses were probably too small. In thorium-X treatment the opposite condition was present. Even the Röntgen treatment of blood diseases had a thorny path to overcome. Certainly there have been more accidents in this field than have become known. My belief is that thorium-X treatment will eventually prove very valuable, although as yet it is inferior to Röntgen treatment and to the radium emanation treatment. The possibility of very exact dosage, the rapidity of the action, the convenient form of application, and, not least, the relative cheapness of thorium preparations, are the basis for this opinion.

### BIOLOGICO-THERAPEUTIC VIEWPOINTS.

We now turn to the enumeration of the biological activities of radioactive substances as far as these are important for treatment.

A. *Calorie Metabolism.*—Emanation in many persons increases the respiratory interchange of gases. The subjects of the experiments were left daily for two hours in the emanatorium with doses of 119 to 440 M. U. for each liter of air; the increase of the basic metabolism amounted to as much as 27 per cent. This is a result which hitherto could be obtained through thyroid feeding only. The researches have in prospect that we can use with advantage radioactive substances for the treatment of certain forms of obesity (endogenous obesity). It is probable, however, that thorium-X is better suited for this purpose than radium emanation, because therewith one can bring the organism more readily under the continued action of radiation. On the other hand the researches teach us that radium and thorium should be avoided in severe diabetes, in Basedow's disease, and in febrile affections, for in these diseases there exists already an unwelcome augmentation of metabolism.

B. *Metabolism of Albumin.*—In most of the cases thus far investigated there has been found a certain increase of the metabolism of albumin, a determination which may be made useful for the therapy of true gout and many phenomena of old age.

C. *Carbohydrate Metabolism.*—During the action of emanation the respiratory quotient increases, often indeed very notably. This indicates that carbohydrates are mobilized and oxidized in increased quantities. It does not follow, however, that radioactive therapy should be applied in diabetes mellitus, for in diabetes we have rather the duty of restricting the production of sugar, while for stimulation of sugar-oxidation no reason is present. We would probably, by radioactive therapy, excite the production of sugar instead of retarding it. Researches on diabetes justify our scruples. The excretion of sugar for the most part increases, especially in severe cases. The acetonuria also increases, probably on account of the impoverishment of the liver in glycogen.

D. *Purin Metabolism.*—Very noteworthy are the changes in purin metabolism. As the first researches of Gudzent and Löwenthal showed, emanation therapy favors in a high degree the excretion of uric acid. Small doses even suffice to demonstrate this influence. In large doses we saw the uric acid increase by more than 100 per cent. The same influence belongs, as was to be foreseen, to thorium-X and here also thorium-X may in time prove itself to be the more efficacious and the more convenient stuff.

At the present time we do not know whether the increase in the uric acid excretion rests exclusively on a facilitation of the latter or, simultaneously, upon an increased production. The latter, however, is very probable, in view of the great amounts of uric acid which in a few days amount to a larger quantity than could have been stored up in the body of a healthy person. In these changes of purin metabolism the influence of radioactivity upon the energy of fermentative processes should probably have asserted itself. On the other hand, processes in the leucocyte apparatus should also play a notable rôle. This will be considered later.

It naturally followed by reason of these determinations to apply radium therapy to uric acid gout, and Gudzent succeeded in showing that even weak emanation mixtures essentially contribute to purify the blood of uric acid. It is, indeed, difficult to determine whether in the cases reported by Gudzent the disappearance of uric acid from the blood is alone to be set down to the credit of emanation, for in all cases other proved therapeutic measures, especially feeding with purin-poor diet, have also been applied. The results of blood analysis are very interesting and important from the theoretic standpoint. From the practical standpoint, however, I must say that the significance of quantitative uric acid determinations in the blood have of late been strongly overestimated. We should not make the uric acid content of the blood a measure for the safety or danger of the gouty subject. The blood analysis has especially a diagnostic value; if one investigates for uric acid the blood of a subject with normal kidneys, who has for a long time taken a diet rich in purin bodies, the result—it is true—will not absolutely guarantee that we have to do with a gouty patient, but will give us a very valuable hold on the case. This determination is especially important in gouty myalgia and neuralgia, which often precede for a long time the typical gouty attack.

Moreover, I really doubt whether the methods of uric acid determination in the blood now in use give trustworthy results.

It is probably not unnecessary to note that experience—thus far—does not encourage us to apply radioactive therapy in so-called renal gout, that is, in uric-acid concretions. The increased determination of uric acid to the kidneys constitutes indeed a contraindication. Moreover, we have several times seen hemorrhages in the kidneys attending the ema-

nation treatment of renal lithiasis. This may be a coincidence. However, I mention it.

As to what now concerns the results actually reached in gout, I would like to express myself with reserve. Many are filled with enthusiasm, while others have criticized the results loudly. From the scanty gout material in my university clinic and from the somewhat more extensive gout material in the private clinic I learn that, before all, the pains in the chronic atypic forms of gout, including the neuralgias are very favorably influenced; and that even chronic joint swellings are in this form of gout notably diminished in size. In most cases medium amounts of emanation and above all very strong drinking cures were applied. On the other hand, I have not observed any influence on quiescent tophi. As in the case of articular rheumatism, it often happens that at first the pain and swelling increase. This is, however, a good prognostic sign for a favorable result of the treatment.

My verdict is less favorable, so far as my personal experience extends, in regard to an influence over typical gout, occurring in acute attacks. Upon the attacks themselves radioactive therapy had no curative influence. The attacks pursued even a more severe course than before. The prophylactic action was also slight.

It seems to me that patients will have to persist with the dietetic treatment of gout as the principal factor in the therapy of that disease and will at the same time, be able to greet the favorable influence of radioactive treatment upon the tormenting pain as an essential and welcome auxiliary.

As to how far in future the difficult emanation treatment can be replaced by drink and injection cures with thorium-X the future must teach. In principle both methods act in the same sense, but one is not yet in position to estimate the superiority of one over the other.

E. *Influence Upon the Blood.*—1. Erythrocytic anemia.—Under the influences of large amounts of emanation and moderate amounts of radium salts injected subcutaneously, and above all after injections of small quantities of thorium-X there occurs in healthy human beings and animals *hyperglobulia*, which persists for weeks and may last far beyond the time of treatment. The action of the emanation in this respect is much weaker than that of the radium salts and of the thorium. In persons who work much with radium in bulk or in solutions we see the same phenomena.

Upon the other hand, radioactive substances are also dangerous to the red corpuscles. This is a matter of quantity. It occurs just the same in the case of radioactive substances as that of other medicaments that we have known for ages, such as arsenic. Small doses stimulate, large ones retard formation of blood. Especially dangerous are the radioactive substances, when there exists a previous lowering of resistance of the red blood corpuscles. For example, in a case of Banti's disease, where we had shown such a lowering of resistance, the red corpuscles under the influence of thorium-X were reduced in a few days from 3.2 millions to 1.8 millions. I may recall also the Berlin mishaps in which death set in with the development of a strong hemorrhagic diathesis. On the other hand, the marked influence on the blood and the erythrocytic apparatus justifies the application of thorium-X in pernicious anemia. The number of observations is still too small to permit of a final judgment. One must also remember that rapidly favorable changes often occur unexpectedly and spontaneously. I described these rapid changes long ago when I was assistant at Gerhardt's Clinic under the name of "blood crises." Although naturally failures were not missing, experience thus far justifies us in fair hopes. However, one must be extremely careful and only feel one's way. After what we have seen, one should first restrict the treatment to cases in which the blood picture shows that the power of regeneration of the bone-marrow has not yet been exhausted to the utmost. Cases in which no longer normoblasts pass into the blood appear to be unsuited for treatment. In every case one should previously prove the capacity for resistance of the erythrocytes.

The Leucocyte Apparatus, Leukemia.—With the leucocytes the case is similar to that of the red cells. We should first, indeed, call attention to the fact that small and even medium doses of radium emanation have, as a rule, no influence whatever on the total number of leucocytes. In large doses of emanation we almost always see a certain degree of hyperleucocytosis. The number of leucocytes can increase twofold and upwards and this alteration of blood persists for a long time. Thorium-X in small doses exerts the same influence as large quantities of emanation.

As in the case of the erythrocytes the effect is reversed as soon as we further increase the doses. Leucopenia then develops. In order to reach this condition with emanation, it is indeed necessary to give doses of such size as never come in consideration in therapeutics. The dose of thorium-X, however, which can cause a marked destruction of the leucocytes is very low. It lies closely above the value, which excites the increase of leucocytes. We often see at first an increase, followed promptly by a marked decrease. In animal experiments we often saw leucocytes disappear entirely from the blood. Autopsy showed a high degree of destruction of the pulp of the spleen and a disappearance of the adenoid tissues; further a high degree of degeneration in the adrenals and in the entire chromaffin system, besides hemorrhages in the colon. Despite the dangers which threaten from lack of caution in dosage, medical art is able to utilize this quality of thorium-X. The thought of testing it in leukemia lay near. This was done in the spring of this year, simultaneously at my clinic and the Kraus clinic. As far as I can judge of the results myself, the continuation of the therapeutic studies strengthened essentially the hopes, which we expressed at the Congress of Internal Medicine for these methods of treatment. In beginning cases of leukemia, where an already marked enlargement of the spleen has existed, but the number of leucocytes has not exceeded one-half million, the thorium-X treatment has thus far not left us in the lurch. It seems that the results appear more promptly and are more permanent than with Röntgen treatment. We have in any case to state to our great satisfaction that our armamentarium against leukemia has become enriched with a powerful weapon. Naturally, however, thorium-X is no universal remedy for that disease. That processes, which have advanced very far, can be bettered or cured, is thoroughly improbble. Already there have been such failures and we, too, have seen them in far advanced cases. This, however, should not discourage us. The same thing occurs in all chronic diseases the solution must lie in: *principiis obsta.*

As you have seen, the therapeutical application

of radioactive substances, for the stimulation of the total metabolism of the obese, for combating uratic gout, for the improvement and possible cure of severe anemia and leukemia has been brought into the best harmony with what we know of the general biological action of these substances. Even in the healthy results occur which point the way to the therapy.

*Other Activities.*—The therapeutic application of radioactivity to internal medicine is, however, not yet exhausted. We have in the meantime learned of remedial activities, which cannot yet be explained by theory, or, at least, only very imperfectly.

Rheumatic Troubles.—In the first place we should mention the influence on rheumatic processes. By far the most patients, that in the course of the last two years have thronged the emanatoria for supposed gout, were not actually sufferers from uric acid diathesis, but from a subacute or chronic nonuratic arthritis; especially from arthrosis deformans. I say intentionally "arthrosis" and not "arthritis," for in my opinion this disease is due to disturbances of the internal secretion, which causes trophic and degenerative changes of the joint so that inflammation, that is arthritis, synovitis, myositis, osteitis are only secondarily added. The confusion between the rare gouty and the much more common nongouty affections of the joints, especially arthrosis deformans, is the rule with the public: but physicians often commit the same error, and, indeed, very much to the disadvantage of the patients, because the wrong diagnosis of gout very often leads to rigorous dietetic measures, which in the long run weaken the patients extremely.

This confusion has had the good effect of leading the rheumatic subjects to radioactive therapy, upon which it appeared that these patients, while not indeed regularly, but in a surprising number of cases, obtained great benefit from this treatment. The results extended to a lessening and removal of the pain, to retrogression of effusions and synovial swellings, to restoration of locomotive power. As a rule there first appears an inflammatory reaction, and it is just these cases which apparently become worse at the outset that promise the best results later. In some cases weak emanatoria suffice, but I must emphasize the fact that we did not become convinced of the great importance of radioactive therapy of chronic nongouty joint affections until we strengthened the emanation essentially. In passing to 25 M.U. per liter of air, the results were already notably more favorable than with the small doses of 4 to 8 M.U. per liter. The results further improved and were in many cases quite astonishing when we went as high as 200 to 500 M.U. in a liter. The good results were distributed quite irregularly among the different forms of subchronic and chronic nongouty affections of the joints. They included also, to some extent, cases of acute articular rheumatism and the residues of the same. I might indeed say that it was in these very cases in which an acute articular rheumatism had been essentially cured—while still leaving behind pains and thickenings of the soft part in individual joints—which showed the most satisfactory results. The same experience has been reported from the Joachimsthal Radium Kurhaus. Nevertheless, it seems premature to indicate to-day which definite clinical forms of chronic rheumatic affections are more and which are less especially adapted to radioactive therapy. We must yet collect many careful observations before we can set up such rules.

In other antirheumatic cures the case is the same. We cannot say upon certain and convincing grounds that this or that particular case of chronic rheumatism will be best treated at the indifferent warm springs, or by hot brine baths, or mud baths, or turkish baths, etc. For the most part we must experiment as to which bath is most suited to the patient. Personal experience, or I might almost say, therapeutic instinct of the experienced physician, often leads to the selection of a cure much better than scholarship and theory.

With a few words let me mention as a second group, *muscle pains and neuralgias.* In an endlessly greater number of cases than the statement of text books allow us to suppose and than the practitioner assumes, these painful affections depend upon metabolic disturbances or intoxication. In a predominating number of cases the toxins are of intestinal origin. Naturally in these cases one would obtain a much better and above all, a much more permanent result, if one ascertained and combated the cause. We may say that the greater portion of myalgias and neuralgias have not only a physical but also a chemical element which must, before all, be treated by diet. It is often necessary to make a very careful study until the causes can be clearly understood and a rational dietetic therapy founded upon them. Nevertheless such an etiological therapy will gladly accept the aid of physical measures.

Neither in combating chronic arthritis nor in combating neuralgias and myalgias should radioactive therapy seek to make superfluous the time-honored curative methods and supplant the famous nonradioactive curative springs and health resorts. Aachen, Aix-les-Bains, Franzensbad, Marienbad, Homburg, Leuk, Ragaz, Wiesbaden, Wildbad, Salzschlirf, Schlangenbad, Trenczen-Teplitz will not cease to be antirheumatic and antineuralgic health resorts of the first rank, although their waters contain only traces of radium emanation. Who would blot them out from a therapeutic register behaves like a faddist.

Besides these timehonored, curative factors radioactive therapy will, however, doubtless conquer for itself a respectable place. When we ask which form of radioactive therapy we should choose, my opinion is one should first direct one's attention to radioactive baths. At health resorts where radioactive springs flow, inhalation and drink cures can cooperate, especially in Joachimsthal; and with these different methods united with other favorable hygienic and dietetic auxiliaries of the health resort, the prospects of good results are doubled and trebled. One should not throw overboard the experience that in the above mentioned group of diseases treatment at health resorts, hospitals, and sanatoria always shows better average results than treatment at home by various physical methods. I do not believe that the emanatoria which have been erected in the large cities and which will still be erected, will succeed in the long run in overthrowing the repute of the approved health resorts. A number of indispensable auxiliaries which health resorts and sanatoria control cannot be obtained at home. On the other hand, I believe that injections of radium salts and preeminently injections and perhaps drinking cures of thorium-X, are destined to play a great part in the therapy of the said diseases. Our favorable experience with thorium-X relates to chronic articular rheumatism, sciatica, occipital neuralgia, migraine, and tabic pains. The

latter often react with astonishing promptness to the injections.

Sleeplessness, Nervous Overexcitability, etc.—In the third place I cite these also among the conditions which are often surprisingly favorably influenced, in the absence of our ability to interpret the internal mechanism of the action. Whoever has treated patients in emanatoria can confirm this experience. It impresses itself upon us with such convincing force that the thought which first comes near of a suggestive action must give way.

Sexual Potency.—Even in the beginning of radioactive therapy some favorable results were reported in reference to sexual potency. We have devoted special attention to this question, and it seems to us —if we group together our own results with those reported by others—definitely established that radioactive substances may exert an essentially stimulating influence on the generative glands and reflex apparatus, naturally provided that the functional possibilities of the latter are preserved.

In regard to the action of emanation upon the potency, we have the definite impression that permanent success (which doubtless lies beyond the confines of the possibilities of suggestion) is obtainable only through large doses (50-100 M.U. in a liter of air); and as a rule prolonged treatment is also required. Especially striking was the result in some patients with mild diabetes mellitus. Naturally these patients pursued simultaneously suitable antidiabetic measures, which caused them to be free from sugar. It is, however, well known, that in mild diabetes whenever a pronounced disturbance of potency has once appeared, the most careful dietetic and other measures must be used for a long period before the potency is essentially improved. Strong drink cures (30,000-60,000 M.U.) following the dietetic treatment seemed to hasten this improvement to an extraordinary degree. Injections of thorium-X promise to be still more favorable. One should not, however, begin with radioactive therapy until the patient has become free from sugar and has remained thus for a long period. For radioactive substances antagonize efforts to free the organism from sugar, and in severe cases increase the glycosuria.

Blood Pressure.—That high blood pressure is lowered under the influence of emanation belongs likewise to the oldest observations. This applies to arteriosclerosis and high pressure nephritis. I must express my astonishment as to the claims made that this effect regularly follows the application of weak emanation mixtures. I assume that other influences have cooperated here and that the lowering of blood pressure was incorrectly referred to emanation. According to our very extensive experience one does indeed see lowering of blood pressure during and after treatment with weak, medium, and strong doses of emanation, but we cannot reckon with certainty or even a certain degree of probability here, and we believe that almost always a certain amount of the lowering of blood pressure must be attributed to the accompanying therapeutic practices.

The state of affairs is otherwise in the much more powerful injection of thorium-X, the blood pressure lowering action of which was first shown by S. Kraus. We can fully confirm this statement. We also saw headache, pressure in the head, vertigo, and congestion (such as often accompany hypertension) disappear.

For interpretation we would recall the fact that larger doses of thorium-X injection have a bad influence upon the adrenal tissue, which governs by its secretion the blood pressure in some way.

*Contraindications to Radioactive Therapy.*—Which one of the indications that may be derived from previous experience with radioactive therapy will stand the test of future empirical and theoretic criticism, cannot naturally be reviewed as yet. However certain contraindications can even now be formulated. I will mention them here only briefly and add that I support myself essentially upon the experience of my clinic:

1. Conditions of cardiac weakness of every kind.
2. Neuroses of the vegetative nervous system, especially the sympathetic and severe neurasthenia.
3. Morbus Basdowii, diabetes, febrile conditions.
4. Tendency to hemorrhages of every kind, especially menorrhagias, metrorrhagias, hemoptysis, hemorrhagic diathesis, hemophilia.
5. Far advanced affections of the erythroblastic and the leucoblastic systems. (In contrast to early stages, which are excellently suited to this treatment.)
6. Cachexias of every kind (pronounced unfavorable influence on cancerous cachexia).
7. Senile marasmus. (In contrast to the beginning phenomena of old age, which are excellently suited to the treatment).

*Valuation of the Methods of Radioactive Therapy.*—Just as little can be said to-day to differentiate sharply the indications for radioactive therapy, so little can be said definitely as to which of the methods described will prove itself of most value. In the order of intensity we may group the methods thus far known as follows:

1. Thorium-X Injections.—These are controllable to the most delicate extent from the smallest inactive doses to those highly dangerous to life. However, the activities are so manifold and in part so violent, and the quantitative relations between dose and action have been studied so little that this therapy cannot yet be recommended for general application.

2. Thorium-X Drinking Cures.—The same may be said of thorium drinking cures. They are probably not inferior to the injections. As an unpleasant collateral effect may occur a strongly local irritation in the gastrointestinal canal. This may indeed be avoided by proper precautions.

One would not need to be much of a prohpet to predict that the powerful thorium-X treatment is the most promising of all methods thus far known. When it is better controlled it will be suitable with sufficient precaution for home treatment as well.

So far as we can survey the field its domain will be all those affections in which we can use practically large quantities of radioactive energy. These are before all the diseases of the blood, severe anemia and leukemia. Here one can accomplish nothing with the strongest emanatoria. Thorium treatment will however also extend to the treatment of chronic arthritis, arthrosis deformans, uric acid gout, myalgias and neuralgias. It will surely also gain ground in the treatment of disturbances of sexual power. The methods to be mentioned later often show themselves too weak in these affections.

3. Injections of Radium Salts.—In theory these are not inferior to thorium injections in power, but in order to attain the results which are obtained by medium thorium injections, large amounts of radium are required, which from the standpoint of the enormous expense, are for the time being out of question. In the form and dose in which radium in-

jections have thus far been used, they cannot be designated as very strong. The doses were frequently so small that very often it was rather more the name of radium than radium itself which was the bearer of the therapeutic energy.

4. Combination of Strong Radioactive Spring Baths with Emanatoria and Drinking Cure.—This appears to me to be the form which the practical physician to-day will take up by preference when he wishes to refer his patients to unobjectionable and certain measures. The most important indications here are:

(*a*) Genuine uric acid gout, with the provision that throughout all the dietetic measures are to be appraised as still higher than the radium treatment.

(*b*) Nongouty arthrosis of various causes with the provision that they are beyond the stage during which rest, antirheumatic remedies and a certain amount of patience secure excellent results.

(*c*) Myalgias and neuralgias, with the provision that they are not conditioned and maintained by disturbances of metabolism and intestinal intoxication; that is, the radioactive therapy is indicated where other physical measures also are indicated and where chemical methods are out of place.

(*d*) Disturbances of sexual power with the provision that all indications which are furnished by the original metabolic affections of the most varied kind have already been taken into account. The thorium-X methods seem, however, to be superior to the baths.

(*e*) In the beginning phenomena of old age, without actual disease. We recall that Gastein, centuries ago, enjoyed a reputation above all other localities for its rejuvenating bath. Patients returning from Joachimsthal are heard to-day to boast that the spring there is the "fountain of youth."

(*f*) In mild forms of neurasthenia and in nervous insomnia and in nervous pruritus.

5. Strong Emanatoria.—In the fourth place in this scale are to be mentioned the really strong emanatoria, that is, such as guarantee a minimum content of 25 M.U. in a liter, and which permit a still further strengthening. As the erection of such emanatoria for the time being encounters insuperable pecuniary difficulties, there comes into question as a substitute the small portable emanation apparatus, which, however, must be essentially improved before much can be expected of it. The emanation-bed (Neu Langfeld) may also be mentioned here.

6. Medium Emanatoria (12 to 25 M.U.).—These rank in the sixth place and further the drink cures with really strong solutions of radium emanation. (30,000 to 60,000 M.U. per diem). As far as we regard only a local action, I reckon here also the high priced radioactive pillows and compresses.

7. The Weak Emanatoria (8 to 12 M.U.).—The weak emanatoria, or, in other words, the mostly used form to-day of radioactive therapy, deserve to be mentioned in the seventh and last place. Much money has been squandered and what is worse, much good confidence has been imposed upon by the premature erection of many emanatoria, for there is no question that many of these have at their disposal much too weak gas mixtures, mixtures which lie notably below the minimum of their working capacity. One was at first too enthusiastic, one overlooked the quantitative relations between cause and effect, and one drew the circle of indications too wide. One stumbled upon the new methods before they were sufficiently elaborated by physiology and pharmacology.

In the meantime matters have become much better. One now is warned by the criticism, which has been brought forward against the weaker and weakest emanatoria. If now a retrograde wave sets in, this can do no harm at all. In radioactive therapy so much good lies hidden that it undoubtedly will be explained and perfected, and, as victor, will emerge from the strife of opinions. This does not lie indeed in the interest of the different mercantile companies, but the more in the interest of the new method itself, of physicians and of patients, when we demand that the entire radioactive therapy shall be elaborated and rated much more thoroughly by physiology, pharmacology, and the clinic, before it is given general application. The weak emanatoria indeed do no harm. They are often not much more than a therapeutic byplay. But it is quite otherwise with the stronger radioactive methods. With them the greatest precaution is necessary, for their healing powers on the one side, their danger on the other side, are not inferior to those of the strongest alkaloids.

---

## THE PROGNOSTIC VALUE OF THE RINNE, WEBER, AND SCHWABACK TESTS.*

By A. B. BENNETT, JR., M.D.,

WASHINGTON, D. C.

For the past two years I have had a growing curiosity to know the real value of the tuning-fork tests relative to their prognostic truthfulness. In reading otological works one will find much space given to the description and interpretation of the tuning-fork tests in cases of impaired hearing, and usually at the close of the description there will be a confession on the part of the author that the tests are of little value. The tests are plausible and seem based on sound physical laws, and, what is more, they have been discovered by men of whose integrity we are assured and who have given the tests to the profession after careful study and clinical application. Therefore when I was asked to read a paper before this Society I thought that a review of these tests and an analytical study of a few cases might be of interest.

The principles of the tests of hearing are:

First. The normal range of hearing is between 16 and 48,000 double vibrations per second.

Second. When there is an interference in the conduction apparatus, hearing for lower tones is lowered or lost.

Third. When there is an interference in the perception apparatus, hearing for the higher tones is lost.

Fourth. Normal ears hear twice as long by air conduction as by bone conduction.

Fifth. When the conduction apparatus is diseased bone conduction is longer.

Sixth. When the perception apparatus is diseased bone conduction is diminished and the relative time for air conduction is lengthened.

I have found nothing in literature that contradicts these principles and many of the tests are based upon them.

*The Rinne test* is described by most writers as the comparison of the hearing of the tuning fork by air conduction and by bone conduction. If hearing by air conduction exceeds that by bone conduction in a deaf ear, it is called a Rinne positive and

*Read before the Medical Society of the District of Columbia, Oct. 16, 1912.

indicates a nerve deafness; and if hearing by bone conduction exceeds that by air conduction in a deaf ear, it is called a Rinne negative, and indicates middle-ear disease. Ballinger states that the difference must be recorded thus: "If bone conduction lasts 25 seconds and air conduction 15 seconds, it is a Rinne negative 10 seconds. If air conduction lasts 10 seconds longer than bone, it is a Rinne positive 10 seconds." Ballinger says that an A-1 fork should be used, while Politzer states that a C-1 or C-2 or C-3 fork can be used.

*The Weber test* is the using of a C-2 512 V. fork, placing it on the median line of the skull, forehead, teeth or chin. When there is disease or interference of the sound conduction apparatus, the sound of the tuning fork will be accentuated on the affected side, but if the deafness is due to labyrinthine disease the sound will be heard on the normal side. "The test is not applicable where there is both labyrinthine and middle ear disease or where both middle ears are diseased."

*The Schwaback test.* Schwaback discovered that "A fork vibrating in contact with the cranial bone was heard longer in the affected ear, referring to middle ear disease, than in a normal ear. The opposite is true when the auditory nerve is affected, the fork then being heard longer by the normal ear." For example, the fork is struck and placed on the patient's mastoid, and when the sound ceases it is transferred to the examiner's mastoid. If it is then heard it indicates labyrinthine disease in the patient. If not heard the examiner first places it on his mastoid and when the sound ceases places it on the patient's mastoid. If heard by the patient after the examiner's normal ear has ceased to hear it, an obstruction of sound conduction, but not disease of the auditory nerve, is indicated. Politzer values this test as diagnostic of nerve involvement and prognostic for recovery under treatment, when the sound perception is prolonged through the cranial bone. This test is valuable as it compares with a known normal the bone conduction power, and it can be easily and quickly performed.

These are the three most important and well known tests, and the tests that I am going to especially consider in this paper. However, I will describe two other valuable tests.

*The Gellé test* for movability of the foot-plate of the stapes, which is accomplished by compressing the air in the external auditory canal with a Politzer bag while a vibrating fork is held against the vertex or the bag, preferably the bag. At the time of the compression the perception for the tone of the fork is greatly diminished in a normal ear, owing to the increased pressure within the labyrinth. If there is ankylosis of the foot-plate there will be no increase of labyrinthine pressure and no change in the intensity of sound. On the other hand if there is marked deafness and the tone is diminished with each compression, it signifies that the foot-plate is movable and that the deafness is due to labyrinthine disease.

*Bing test No. 2* was devised for the purpose of differentiating between ankylosis of the foot-plate of the stapes and adhesive bands or other pathological conditions which hinders the malleus and incus in transmitting sound waves. It is the entotic use of the speaking tube. The test being made by comparing the hearing of a patient through a speaking tube applied to the external meatus and one applied to a eustachian catheter in place. If the sound is more distinct by the catheter, the foot-plate is movable while the other ossicles are fixed or hindered.

My desire to bring out especially the clinical relation of these tests to one another and their prognostic indications compared with the actual subsequent history of the cases, caused me to use as material the clinical histories of cases of chronic catarrhal otitis media in which I had recorded at least three tuning-fork tests with the hearing distance and after treatment at a subsequent period made another record of the hearing distance. This limited me considerably as I could not use the records of cases in which there was simply an examination record, nor cases in which I had omitted recording at least three tests.

I found fifty-three record cards that fulfilled the requirements of this paper, which means the analysis of tests upon 106 ears. There were twelve ears that presented symptoms of chronic catarrhal otitis media, but had normal hearing power. All twelve showed a Rinne positive, four showed a Schwaback middle ear, seven showed a Schwaback labyrinth, and one showed a Schwaback normal. In these six cases with normal hearing, the Weber was accentuated to one side twice and did not lateralize in four cases. In the 94 ears with impaired hearing, the Rinne test indicated middle ear disease in 23 ears, 18 of which improved and 5 were unimproved. This gives a favorable prognosis a 78 per cent. chance of being correct. The Rinne test was positive, indicating nerve deafness in 71 ears, 49 of which improved, and 22 were unimproved, giving an unfavorable prognosis a two to one chance of being wrong.

The Schwaback test indicated middle ear disease in 39 ears, 32 of which improved and 7 were unimproved, giving a favorable prognosis an 82 per cent. chance of being correct. The Schwaback indicated a labyrinthine disease in 55 ears, 35 of which improved and 20 were unimproved, giving an unfavorable prognosis almost a two to one chance of being incorrect. The Rinne agreed with the Schwaback, indicating middle ear disease in 19 ears, 16 of which improved and 3 were unimproved, giving a favorable prognosis an 84 per cent. chance of being correct. The Rinne agreed with the Schwaback, indicating labyrinthine or nerve deafness in 51 ears, 33 of which improved and 18 were unimproved, giving again an unfavorable prognosis almost a two to one chance of being wrong. The Rinne and Schwaback disagreed in 24 ears, 19 improved and 5 were unimproved.

The Weber test when applied to the cases where both ears were of impaired hearing, accentuated to one side in 35 cases and did not lateralize in 12 cases. Twenty-seven of the ears in which the sound was accentuated improved and eight were unimproved. The Weber test agreed with the Rinne test alone indicating middle ear disease in one case and that improved. It agreed with the Schwaback test alone to indicate middle ear disease in six cases and all improved. It agreed with both tests to indicate middle ear disease in six cases, five improved and one unimproved. This totals 13 cases in which the Weber agreed with either the Rinne or Schwaback or both to indicate middle ear disease and 12 improved. The Weber test disagreed with both tests in 18 cases, 14 improved and 4 were unimproved.

A glance at this analysis would certainly cause one to doubt the wisdom of relying upon tests that give such contradictory evidence, and I will admit I have only a partial defence to make for them.

A Rinne test which is negative, bone conduction being longer than air conduction, indicates middle ear disease which partly or entirely should be benefited by treatment. In this series of Rinne negative ears there was an improvement in 78 per cent. which is a good proportion when one considers that there is a certain number of catarrhal otitis media cases that will not improve owing to the long duration of the disease with presence of firm adhesive bands that resist all forms of treatment. A Rinne test which is positive, air being longer than bone, indicates nerve deafness, which with a few exceptions would mean an unfavorable prognosis. Yet in this series of 71 Rinne positive ears, 49 improved, which places little value upon the prognostic ability of this test when it indicates disease of the perception apparatus. I feel that there is an error in the description and application of the Rinne test to account for this discrepancy. The Rinne test is based upon the principle of hearing that in a normal ear air conduction is twice the length of bone conduction. Any variation from this proportion is abnormal and should indicate a nerve or middle ear condition. It then is readily seen that to simply state that a Rinne positive is better air conduction than bone conduction, and indicates a nerve deafness, is in error, for it places all normal ears as Rinne positive, and it also includes many approaching negatives as positives. I may make this clearer by supposing the total hearing time for the tuning fork to be 20 seconds, then bone 10 seconds plus air 10 seconds, would be normal. Any shortening of the time of bone conduction and relative increase of air conduction, such as bone 8 seconds plus air 12 seconds, or bone 4 seconds plus air 16 seconds, etc., would certainly be positive and indicate a nerve deafness. On the other hand a lengthening of bone conduction and a relative decreasing of air conduction, really indicating a middle ear disease, would be recorded as a positive, because air conduction was actually longer than bone. For instance, bone 12 seconds plus air 8 seconds, is really a negative, but is called a positive. Bone 18 seconds plus air 2 seconds, is really a negative, but is called a positive, air being longer than bone and under the usual description of the test would be called a positive and indicative of nerve deafness. One step further and bone conduction is longer than air conduction, for example, air 18 seconds plus bone 2 seconds, or air 8 seconds plus bone 12 seconds and we have a well recognized Rinne negative test. I will admit that the intensity of sound from the tuning fork when it ceases to be heard will be the same whether or not a hard or soft blow is given the fork, so that the most significant series of figures is the plus series, but with care and judgment a uniform blow to the fork can be adopted and an estimation made of the proportion of hearing time by bone and air conduction for that particular stroke of the fork. This in a way explains the error between the test prognosis and the results of treatment in my Rinne positive series. Doubtless in many of my recorded positives the bone conduction was lengthening although shorter than air conduction. The twelve ears that had normal hearing all gave a Rinne positive which was more than probable a Rinne normal.

*The Schwaback test* is based on the principles of hearing which state that when the conduction apparatus is diseased, bone conduction is lengthened, and when the perception apparatus is diseased, bone conduction is shortened. In this series of ears 39 showed a longer bone conduction than normal, indicating a middle ear disease, and 82 per cent. improved, showing that where the Schwaback indicated middle ear disease a favorable prognosis was justifiable, though a small number were past help. In 55 ears the bone conduction was shorter than normal, indicating disease of the perception apparatus with an unfavorable prognosis: 35 improved notwithstanding the indications and 20 fulfilled an unfavorable prognosis. This evident unreliability can be explained by first admitting that the tuning fork tests in relation to the perception apparatus do seem to be uniformly unreliable, and, secondly, stating that the impaired hearing in many of these cases was probably due principally to a diseased perception apparatus, and partly also to a middle ear disease. Therefore, treatment directed to the middle ear disease increased the hearing to the extent that the middle ear disease was relieved and a limited miprovement was obtained.

Considering the Rinne and Schwaback tests as they compare with each other it is evident that where they agreed in indicating the part diseased the proportion of ears that fulfilled the prognosis was about the same as with the tests separately, but in 24 out of 94 ears they differed absolutely in their indications.

In regard to the Weber test I have only considered the ear in which the sound was accentuated, as it is that side which is diseased in the middle ear and which would receive a favorable prognosis The Weber test is only valuable in indicating disease of the perception apparatus in unilateral deafness when the sound is accentuated in the normal ear. In 47 cases of bilateral impaired hearing, the Weber accentuated in 35, and of these 27 improved on the accentuated side. This gives about the same proportion of improved over unimproved when the test indicated a middle ear disease as from the other tests under the same conditions. However the Weber disagreed with both the other tests in 18 cases.

If I may draw conclusions from such a small number, they are these: That the study of even this short series of cases seems to show that tuning-fork tests are of value as aids in prognosis when their indications point to middle ear disease. That even with indications of a diseased perception apparatus supported by many tests, we should be guarded in giving an unfavorable prognosis until treatment has been administered and found to be useless, and that probably it is wrong to record the Rinne test as positive or negative, but that the record should show the proportion of time for the plus figure thus: Rinne—Right Air + 10/30; Left, Bone + 5/20. The numerator tells the number of seconds air or bone conduction exceeded the other and the denominator indicates the total time of hearing for the stroke of the fork.

THE FARRAGUT.

---

**Atropine in Tinnitus Aurium.**—Weissenberg calls attention to the good results occasionally obtained from atropine in this affection when its origin is unknown. The author used it empirically and having seen a good result continued its employment with very few negative experiences. Wittmaack has recently stated that some cases of tinnitus ought to yield to remedies which modify the circulation. Atropine has of course an affinity for the blood vessels, which is exhibited in several well known ways. The author prescribes the drug as follows: ℞ Sol. atropinæ sulp., 0.01; aquæ, 15.00. S. Ten to fifteen drops three times daily.—*Deutsche medizinische Wochenschrift.*

# OBSERVATIONS OF THE ATYPICAL CHILDREN IN DR. GROSZMANN'S SCHOOL FROM THE STANDPOINT OF THE NEUROLOGIST.*

By M. NEUSTAEDTER, M.D., Ph.D.,

NEW YORK.

INSTRUCTOR IN NEUROLOGY NEW YORK UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; ATTENDING NEUROLOGIST BELLEVUE HOSPITAL O-P.D.; CHIEF, NEUROLOGICAL DIVISION ST. MARK'S HOSPITAL O-P.D.

Having studied a great many children in New York public schools for a number of years I have come to the conclusion that physical defects *per se*, such as hypertrophied tonsils and adenoids, carious teeth, a deflected nasal septum, if not accompanied by brain defects or disturbances in secretion of the ductless glands, cannot be held responsible for the production of the atypical child. Nor can it be said that this or that particular physical ailment is the only one responsible for the retardation of the child's mentality, for the correction of such only defect has never in my experience yielded any appreciable results so far as the mentality of the child was concerned. I have pointed out again and again that the brightest pupils of school show a ratio of about 12 per cent. without any physical defects, and 88 per cent. have one or more physical defects. In my opinion each atypical child is an entity by itself, and must be individually studied from every point of view, and it will invariably be found that there is more than one factor responsible for its defective mentality. And this statement cannot be made too strong, for the physical defects pale into insignificance beside bad hygienic and social surroundings, bad or improper food, hereditary influences, and brain lesions.

One other factor must be taken into account, namely, the proper teacher. He must not be the one who specializes in any given subject, but rather the one who individualizes and is trained to observe the shortcomings of the child in respect to memory, attention, and imagination. With the aid of the physician such a teacher can bring order out of chaos. And this must be attempted early if success is to be attained, for as the child grows the brain cells adjust themselves to their environment.

They, like any other cell, possess three properties, namely, formative, nutritive and functional. If the first two are interfered with the function of the cell will be impaired. The primary factors that can interfere with such processes are direct influences, such as bad food and faulty hygienic surroundings. Of course, other physical defects may indirectly interfere with the proper nutrition or be a source of irritation, and for that reason should be dealt with, but I do maintain that in every case of the atypical child we must look to the ideational part of the organism, to a brain defect. When carefully examined, we will invariably find that there is one. These defects may be of an organic nature or simply functional. The organic defects may be congenital or acquired, while the functional defects are acquired constantly from postnatal influences. So that in all these cases of retarded ideational function we also note in a greater or lesser degree sensoriomotor defects with corresponding focal symptoms.

In order to explain more fully my thesis and be able to discuss a rational mode of treatment of these cases, let me go over some of the cases examined in Dr. Groszmann's school.

Case I.—R. W., æt. 17; male. Father had venereal disease. An older sister is in an institution for feebleminded; a younger brother has hydrocephalus. Patient was breast fed. Began teething at 9 months; a history of convulsions at that time not available. Had pneumonia, whooping cough, and measles; enuresis nocturna for a long time. Has not complete control over his muscular coordination; his speech is somewhat indistinct, and rather slow and protracted. Was difficult to manage at home, was deceitful, untruthful, and had a proclivity to steal. Was far behind children of his age in school work. In this school he improved considerably in skill and schoolwork.

Physical examination: Pupils unequal and irregular, responding to light sluggishly, but well to accommodation. There is lateral nystagmus, with some divergent strabismus. Spasticity and motor weakness in all extremities. Superficial and deep reflexes exaggerated; Babinski sign present in left foot, and ankle clonus in both limbs. This is evidently a case of cerebral syphilis.

Case II.—W. W., æt. 8; male. A brother of R. W. Is a mixed breast and bottle fed child. Began teething at 7 months; no history of convulsions at this time; learned to walk at 18 months and to talk at 5 years. Language developed slowly, and is still defective. Enuresis noctuna still present. No diseases of childhood so far. Cannot dress and undress completely, and his movements are rather clumsy. Is possessed by phobias. Could neither read, write, nor count when admitted 6 months ago, but makes good progress now.

Physical examination: Pupils are irregular and react very slowly to light and accommodation. There is an old neuro-retinitis with dilated and tortuous veins, and contracted arteries. His head is rather large, of the hydrocephalic type. Superficial and deep reflexes rather sluggish; there is slight ataxia present in all extremities. This is a case of cerebral syphilis with hydrocephalus.

Case III.—D. T., æt. 18; male. Family history given as negative. He is one of three, the other two are normal. Was breast fed. Date of beginning of teething not given. Began to walk and talk at 14 months of age, and very slowly at that. Enuresis nocturna up to 15 years of age. Had whooping cough, but no other disease of childhood. Was very backward. Though slow, is progressing steadily in education.

Physical signs: Pupils irregular and reaction sluggish to light, but well to accommodation. Vertical nystagmus present. Has a right facial paralysis embracing the lower part of the face. There is a partial paresis with spasticity in all extremities, impaired motor power, and athetosis in right hand. Superficial and deep reflexes exaggerated with the Babinski sign in both feet, but no clonus. Case is one of cerebral syphilis.

Case IV.—E. E., æt. 17; female. Father of a nervous temperament; mother died of apoplexy. Paternal grandfather died of tuberculosis; paternal grandmother died of cancer. Patient is the last of eight children. The history of the others is not given. She was born after normal labor and was breast fed. Began teething, walking, and talking at the usual age. At the age of about three years had pneumonia, followed by convulsions. Had measles and whooping cough. Was always and is now undersized. Was somewhat rickety. An *x*-

*Read before the Annual Meeting of the National Association for the Education of the Exceptional Children, at the New York City College, November 1, 1912.

ray of her extremities was never taken. Began to menstruate at 15 years, and rather scantily. Was always constipated. Is rather affectionate and obedient. According to the Binet test a year ago she would be of the intelligence of an 8-year-old child.

Physical examination: Pupils markedly dilated, and do not respond to light and accommodation. Fundi normal, but extremely hypermetropic. Superficial and deep reflexes are exaggerated. The slant of the eyelids gives the characteristic almond-shape appearance to the eyes. The skin is dry and the hair coarse. It seems to be a case of infantilism—a type of cretinism.

Case V.—D. L., æt. 14; male. Family history not obtained. Was a bottle-fed baby, began teething at 8 months, walking at 1 year, and talking at about 3 years. Language developed very slowly. He was operated upon for appendectomy; his tonsils and adenoids were also removed prior to 1911. He is an underweight, and was rather backward in school work, but makes rapid progress.

Physical examination: Right spastic hemiplegia, superficial and deep reflexes exaggerated on right side, with Babinski sign present on that side, but no ankle clonus. There is athetosis with slight astereognosis in the right hand. Ocular fundi normal in both eyes, but there is a hypermetropia of a high degree, different in each eye. This is a case of infantile cerebral paralysis.

Case VI.—H. B., æt. 14; male. Mother neurotic. Patient is first and only child, and was born after a premature labor; was breast fed. He began teething at 6 months, walking and talking at 2 years. He had attacks of convulsions from the age of 3 months up to 3 years. In 1902 he had pneumonia, and made an uneventful recovery. In 1906 he had scarlet fever and diphtheria, from which he also promptly recovered. He is an habitual nail-biter and stammers somewhat. Upon admission was rather backward, but does well now.

On physical examination he presents only lateral nystagmus. In view of the convulsions I should class this case as one of meningo-encephalitis.

Case VII.—H. R., æt. 13; male. Mother neurotic. Patient was bottle fed. Learned to walk and talk rather slowly. He had pneumonia and typhoid fever between the ages of 2 and 3 years. Is somewhat backward, but doing fairly well.

Physical examination: Left spastic hemiplegia with exaggerated reflexes on that side, a diminution of the motor power, ankle clonus, and Babinski. He is a case of infantile cerebral paralysis.

Case VIII.—C. S., æt. 17; male. Father died of general paresis. Patient is one of two children; the other is said to be normal. He was breast fed for the first few weeks, and then bottle fed. Began teething at 6 months. No history of convulsions given. At the age of 18 months he first stood up and at 2 years he walked. At 2 years of age he began to talk. Up to that age he looked like a rickety child. He had whooping cough, measles, scarlet fever, and pneumonia, and recovered from these affections completely. He has masturbated for a time, was backward in school work, and scatter brained. Makes fair progress in school work now.

Physical examination: He is very talkative, but perfectly rational. His pupils are small and irregular, and do not react to light and accommodation. He is hypermetropic. His teeth are typically of the Hutchinson type. There is a motor weakness in the right arm and leg, the tongue deflects to right on protrusion from mouth. There is a right facial paralysis. The deep and superficial reflexes are lively, but there is no clonus and no Babinski. We evidently are dealing here with a case of cerebral syphilis.

Case IX.—J. S. M., æt. 16; male. Father was insane. Mother is dead; cause not given. He is an adopted child, and his history is not known definitely beyond the fact that he learned to talk at the age of 3 years, and that he had scarlet fever. Was markedly backward, but is improving since his admission.

Physical examination: Pupils irregular and sluggishly reacting to light, but well to accommodation, with hypermetropia. There is a slight right facial paralysis embracing the lower part of the face. The tongue deviates to right on protrusion. The motility of the right arm and leg is somewhat impaired, superficial and deep reflexes livelier on the right side than on the left. There is slight athetosis in the right hand, a tendency to the Babinski sign in the right foot, with ankle clonus. He has fits of temper and stammers. It looks like a case of infantile cerebral paralysis and of cerebral syphilis.

Case X.—F. K., æt. 15; female. Mother and father neurotics. Paternal grandmother died insane; maternal grandfather died of tuberculosis; maternal grandparents were related to each other as first cousins. A maternal grandaunt was feeble-minded. No teething history obtainable. Patient was a breast-fed baby. She started to walk at 1 year and to talk at 3 years. Language developed slowly. She had measles, diphtheria, and whooping cough, and recovered from these perfectly. Has not yet menstruated. The child is somewhat backward, but progressing well in her studies.

Physical examination: Pupils are unequal and irregular, the right reacts sluggishly to light, the left not at all, while both react to accommodation well. She has considerable hypermetropia. The superficial and deep reflexes are exaggerated. There is considerable spasticity in both lower extremities, as well as in the upper ones. The Babinski sign and ankle clonus are present on both sides. The teeth are of the Hutchinson type. This is a case of cerebral syphilis.

Case XI.—H. H., æt. 9; female. Family history negative. Was bottle fed. There is no history of teething. She began to walk at 18 months, and to talk at the same time. Between her second and third year she had three convulsive seizures, with loss of consciousness. In 1909 and 1910 she had two more seizures, after which she was listless and feverish for three days. She had measles and whooping cough, and made an uneventful recovery. Four years ago her adenoids were removed. Until then she was a mouth breather. At times she suffers from incoordination in gait, and is unsteady in posture, and would walk up and down stairs on hands and knees. She is very restless and very difficult to handle; is subject to frequent fits of temper, during which she would throw herself upon the floor, kick and scream. She is an habitual masturbator. In school work she is rather bright, far beyond her age, somewhat precocious.

Physical examination: She is hypermetropic, but otherwise her eyes are normal. The tongue protrudes slightly to right. There is a slight facial paralysis on the left side. The motor power in left upper and lower extremities is slightly diminished. There are associated movements in both hands; re-

flexes are lively; there is no ankle clonus, but a tendency to the Babinski sign in both feet. Here we are dealing with a case of psychical epilepsy probably as a result of an old encephalitis.

Case XII.—E. K., æt. 15; female. Maternal grandmother died of pulmonary tuberculosis. Mother neurotic. Her firstborn child has congenital infantile paralysis on the left side. The patient was breast fed; learned to walk and talk early. No history of teething is given. She had measles, scarlet fever, whooping cough, and typhoid fever. There is a history of convulsions at the age of five years and epileptiform attacks a year ago. These attacks come on in intervals of a few months. She is somewhat backward, but progresses favorably.

Physical examination: She is hypermetropic, but otherwise the eyes are normal. There is a slight left facial paralysis, a spastic hemiparesis on the left side with diminution of the motor power on that side. The Babinski sign is present in the left foot, but no clonus. This is a case of infantile cerebral paralysis with epileptiform convulsions. The Wassermann reaction was not obtainable in any case.

These children are living under most ideal conditions. The air is of the purest, their rooms of not less than 1,800 cubic feet capacity are very light and well ventilated; their diet is carefully regulated, and their vegetative functions jealously guarded. Under such condition it is no wonder that the individualizing and observing pedagogue accomplishes good work.

Take for example the cases with epileptiform seizures. It is a well established fact that we can accomplish very little, if anything, with medication, while a great deal is attained with a suitable bland and nonirritating diet. Bad food yields toxic products in its decomposition, which permeate the whole system, producing a mental aberration, and through their irritating influence upon the motor brain cells produce convulsions. The simplest way out of this difficulty is proper food. Habitual constipation, even with proper diet, will produce the same effect as though bad food were ingested. A careful attention to the vegetative functions will obviate the difficulty. Along with this medical attention becomes a valuable adjuvant. And this is true of every other case of the atypical child irrespective of what the character of the lesion may be.

The results attained in Dr. Groszmann's school are due to the combined efforts of the individualizing teacher and the painstaking erudition of the medical examiners whose advice they seek and follow.

111 Second Street.

## BEAUTY DOCTORING.

By HORACE GREELEY, M.D.,

BROOKLYN, N. Y.

While familiarity with our imperfections produces an increasing toleration, which often even grows into admiration, "mine" assuming values in units not thought applicable to another, or even appreciable by him, the realism of comparative views frequently prompts a desire to moderate some of the more glaring defects, and leads many to lend ear to even the most extravagant claims of special ability to effect the wished for transformation.

As pretension is the chief asset of the incompetent, it is by them exploited to the utmost, and seems to be the most effective lure for the would-be-beautiful, as nothing short of a promise of as complete and as wonderful a transformation as Medea effected upon old Æson seems sufficient to content or even to induce them to submit to treatment, which, of the proper kind, intelligently applied, might, in some cases, effect great improvement. But no, as usual the fool by folly led is caught by the greatest glare, and commits that which she is most concerned about to the bungling hands of some ignoramus, who rarely learns enough, even after extended "practice," either to paint a face or dye a coiffure acceptably.

Manicures, hairdressers, barbers, bath-rubbers, masseuses, and even actresses, whose vanity, tempted by trashy newspapers, leads them into ridiculous explanations of how they attained and maintain what is frequently a supposititious beauty, furnish the most recruits to the ranks of these so-called beauty-doctors. It may seem strange that any one should be permitted to do what is actually practising medicine, as defined by the law, without either education or license; yet the public's attitude of indifference, together with the State's recognition and licensing of various procedures encroaching upon this sphere, and the toleration of the prescribing druggist and patent medicine man have so lowered the lay estimation of the healing art as to permit sympathy with, toleration, and even patronage of these people who are really somewhat justified in the claim that their work is thrust upon them. The manicure is required to produce pink, smooth, rounded, tapering nails, and even fingers out of the most unpromising material; to whiten hands, remove freckles, hair, etc., and, unless she at least supplies "hopeful" treatment, is condemned to business failure. Woe to the hairdresser or the aspiring barber who knows no sure method of rejuvenating, tinting, and even of restoring the hair. If a bath-rubber and a masseuse do not confess to a touch sufficiently magic to stroke away a wrinkle, a double chin, or an overplusage of avoirdupois, no matter where located, how may they hope to rise? And so on; the experience of one temptation after another finally turning out a complete "beauty specialist" with claims to suit all comers.

Some will ask why are there no regularly licensed practitioners who do this work? Of course, but their advice and methods, when consulted, are too simple, and their promise not great enough to suit the clientele. In fact, ethical medical men avoid such work, so much has it been brought into disrepute by these people, and are very diffident in giving advice in cosmetics.

In proceeding we will try to show all real possibilities of this work, and both by exclusion and direct consideration demonstrate the baselessness of some of the most far-fetched pretensions.

*The Hair-coloring.*—If one must have a remedy for grayness, there is no other recourse than to artificial staining, notwithstanding a recorded instance of the natural change from black to gray, gray to black, and then again to gray in the case of a man during a period of some five years, and a few other similar though less remarkable suggestive instances. The only effective dyes are those by the use of which a precipitate is formed on the hair, practically a plating or coating; and, as those who have had experience know so well, they never give a satisfactory result; at best a dead, unnatural color is obtained, and very frequently undesirable shading, where sufficient has not been applied or the coating has worn off, leaving a purple, or even a red tint. It has been said that "Indignant Nature

hides her lash in the purple hues of a dyed mustache."

As a preliminary to any staining of the hair it must be washed with an alkali, such as ammonia, and this, especially when applied in strong solution or too frequently, causes it to become very brittle, and consequently soon reduces its bulk greatly. Subsequent to the alkaline wash a solution of nitrate of silver is brushed on, carefully avoiding the scalp (yet for a good result the hair nearest the skin must be thoroughly covered) and allowed to dry in the direct sunlight, during which process it changes into silver oxide—a black. A red tinge or a brown is reached by varying the strength of the silver solution. The same results may be obtained by similarly precipitating an oxide or a sulphide of lead or mercury; but these last named have, when carelessly brushed on the scalp in some quantity, occasionally given rise to symptoms of poisoning. A red tinge is also sometimes given to light hair by the use of an infusion of henna leaves or of logwood. Brown, more or less fugitive, may be imparted by a solution of the coloring matter from the outer husks of the native black walnut, such as the country small boy has such difficulty in removing from his hands in the fall. A light shade of the same is sometimes produced by a preparation of tannic acid which, for the color in question, usually gives better results than the other dyes.

To tinge dark hair, a degree of bleaching must be effected, always by the use of peroxide of hydrogen, and, by varying the number of applications, after the preliminary removal of the oil by the alkaline wash aforementioned, this is made a brown, dark or light according to wish, or even a reddish shade may be left by adroit management. Of course, apart from the tendency to extreme brittleness produced by the alkali, no actual harm is done, if, in the case of the dyes, the scalp is avoided, and we can tolerate the blend of color so frequently obtained. Bleaching is not so troublesome, and can be effected fairly well by oneself without danger, except the resulting brittleness. Yet nine out of ten fail to reach the back and more inaccessible portions of the hair, and always overbleach the front and ends. We often hear blondes complain that their hair is growing darker at the roots or in the back, when nothing but their own unequal applications or failures first to remove the oil from the hair are to blame.

Of course there is no such thing as a hair restorer, and, when once a hair has dropped out from the changes incident to advancing age (and this is the only cause for general falling of the scalp hair, except severe acute illness) nothing will replace it. It is very much like pouring water on a rotten stump, expecting to regrow the tree, to dump the various tonics on one's scalp. Most of them contain nothing possessing even a good pretence of action when applied to the scalp, although some have irritating properties which are supposed to stimulate the local circulation of blood, but for what? The hair-root died before the hair fell out, and there is no known method of reviving it. Recently, however, an enterprising Frenchman has found a way of seeming replacement wherein, as in a child's garden planting, the broken off tops are stuck in. He fastens a hair to a bit of gold wire, and pushes the wire beneath the skin, allowing the hair to protrude, and repeats the procedure till the required number have been placed, or, perhaps, till he or his pin-cushion patient is exhausted. Of course they do not grow and are not expected to do so, and all will soon break off, so that such frequent repetitions of the process are necessary as to make it improbable that anyone except a widower on the trail of the teens would submit.

Quinine, much vaunted as a hair restorer, has no effect whatever, unless in large quantities, when it acts as a mild antiseptic, none in the proportion used in the so-called "tonics"; and the popular egg-shampoo is a poor substitute for soap and water.

Although dandruff is part of a general skin disorder, usually dependent upon general ill health or poor digestion, and is best got rid of by removing the cause, some temporary good may be accomplished by the use of mild antiseptic washes (usually a solution of resorcin), but the sure-cure advertised as due to such preparations is very slow and uncertain in materializing. As the underlying conditions improve the dandruff disappears, and no permanent cure is possible otherwise.

Preparations claimed to curl the hair contain gum-arabic, and those to straighten it, wax; so how each of these might feebly act in the indicated direction is readily appreciated. The plantation darky's corn-silk and grape-vine decoction has never become popular, perhaps only because our hair is inclined to be straight, and our sighs are all for curls. I know a woman who regularly uses the ashes of wood-shavings (secured in long spirals) and who cannot be convinced that those of a fence-rail would do as well, as it is only the lye obtained which, by removing the oil, encourages her curly locks. I hardly think any reader would try a hair-oil, which, if ever used, is best made of castor-oil and alcohol. The much vaunted singeing of hair, to stop splitting, only burns off what a pair of scissors would more easily remove without doing the damage wrought by the heat, which chars or renders very brittle the remaining part of the hair for an inch or more below, and actually does harm.

The face, however, supplies what the French call the *point d'appui* of the "beauty doctor's" prentice-hand, and on it most of his pretensions are lavished. Nearly all the measures employed are both harmless and totally ineffective, comprising applications of lotions of glycerin and water flavored and colored in infinite variety; creams, greasy and greaseless; both lotions and creams variously fortified with one or more of the subterfuges with which empiricism has endowed the pharmacopeia. The glycerin contained in the lotions, while some remains on the skin, acts as a lubricant and, by making it temporarily slightly more pliable, conveys the impression that it may permanently modify it in this direction. Some lotions contain carmine and consequently impart a pink tinge. The grease creams, such as cold-cream, a composition, principally of oil of almonds, flavored with rose-water (although cheaper fats are commonly used), are either modifications of this, or made with a base of wool-fat, vaseline, cocoa-butter, castor-oil, all with varying proportions of wax to add consistency, and frequently a little whale-fat (spermaceti) is thrown in without any good reason. Flavors are given to suit, and many are colored, as "cucumber-cream," which sometimes, besides being dyed light green, has some cucumber juice added to supply the appropriate odor. Why this vegetable is used is hard to tell, unless as it is said to have the odor of rattlesnakes, in imitation of the savages who superstitiously anoint their bodies with snake oil, to make them supple.

Greaseless creams contain gelatin or starch appropriately flavored and colored, and their only use is as a substitute for water when one has an intuitive dislike to familiar contact with that so-called element—of primary education—and so enable her ladyship to cultivate a superficial hydrophobia; but, as they carry away with them, when rubbed off, much of the dirt, they are useful.

A "skin-food" is one of these creams, and is of course nothing but an absolute fraud, having no action in the direction implied, as it is as reasonable to try to fill a pitcher by setting it in a basin of water as to expect an appreciable amount of the fat rubbed on to penetrate the cuticle. Anyway the skin as it is popularly known is not nourished by fatty materials.

"Toilet-milks" are emulsions (suspensions in water) of the various creams, and of course are similar in effect. "Jellies" consist of gelatin, gum-arabic, or starch added to one of the lotions, and are equivalent to greaseless creams.

*Freckles,* which are but points of greater skin color-production stimulated by the increased need of protection from the strong light of summer, are commonly treated by the application of a corrosive lotion, universally a dilute solution of bichloride of mercury, which is usually repeated at intervals of several days until the most superficial layers of the outer skin become detached. The greater smoothness and less stained character of the remainder, together with an effect of the mild irritation, an increased blood supply, produce a slight temporary improvement in skin finish and coloring which lasts for some days. Of course the seat of pigment production lies beyond reach of the method, but at least the superficial coat is removed, and the rest is partially concealed as stated. If such a procedure be used too frequently, and it can rarely be repeated more than once a month, marked actual harm may be done—the skin becoming much roughened and possibly discolored. Really, under the best circumstances, the result is hardly sufficient to save the whole thing from being decried as an absolute fraud. It, however, furnishes a means whereby the customer may be deluded into further patronage, thinking that, as with the imperfect pearl, peeling may reveal a luster unknown before; and although the attempt may not, as with some of these gems, be disastrous, yet, were her ladyship's expectations to be realized, she would have to be all skin like an onion, and would be finally peeled away by the repeated efforts to reach the peach-blow she fondly imagines lies somewhere beneath. Some bleaching of the surface of the skin may be effected by long continued use of peroxide of hydrogen, each time after a good soaping. So called blackheads, large-mouthed skin glands whose oily discharging secretion has become darkened by dirt, may be made to disappear with a good scrubbing with soap and water, although a fat dissolving lotion frequently used will do the work.

*Wrinkles* are due to two causes: One the increasing loss of elasticity from which the skin suffers in common with articles made of rubber, which the more extensively and more frequently they are stretched the less complete their return to their former state and size, and changes in the skin bed, such as the absorption of fat therefrom, alterations in the shape and size of muscles and bones, which latter of course only affect the larger furrows. As there is normally great individual variation in skin elasticity the tendency to wrinkle varies accordingly. The treatment of this condition, apart from the peeling process above detailed, which in the temporary glow and freshness resulting conceals, as spring the ravages of the passing winter, the furrows and ridges beneath, is attempted by applying adhesive plaster, collodion, or even bandages, all of which act by temporarily protecting the skin from the creasing action of the underlying muscles till body fluids have distended the underneath tissue interstices, or have produced this last effect by inducing capillary dilatation, as a plaster does through increase of warmth, or by withholding some of the air pressure, or both. As will be understood from the foregoing it is extremely doubtful whether permanent results can be attained by anything short of permanent treatment, but one thing, however, is certain, and that is that the nuisance involved is never justified by the result, for the improvement is barely noticeable. Some of these special "specialists" "cure" wrinkles by covering all with a nasty smear of paint and powder or the so-called enamel —a suspension of various powders (calamine, a pink, talcum-like substance is a favorite) in glycerin —which is painted on, and, as the glycerin does not dry, neither blows away nor cracks if reasonable thickness is not passed.

Grease paints are combinations of olive or of sweet-almond oil with wax and various colors; often the cheaper kinds are made of other fats with paraffin instead of wax.

All good rouge is prepared in France from the safflower, a plant grown in the East, and its precipitation upon the little china disks on which it is sold is so much of an art that attempts at imitation in this country have been too costly to make competition profitable. Still more is sold than of any other cosmetic, and, even if we decry its use as removing some of the incentive to improve one's health, we cannot pretend that it has any harmful effect whatever on the skin. So let us be content with proclaiming that here a crime is committed only when the criminal is detectible, as is sometimes the case in much graver matters.

A great many face preparations are denominated cerates, which implies a content of beeswax, used to stiffen the ordinary grease-cream, and so act similarly, the only difference being that their greater consistency permits more to be rubbed on, and then not to be so easily rubbed off.

Certain procedures applied to the hands come under our subject, for, in addition to the use of the various lotions, creams, etc., to small or to no purpose, some pretenders claim to be able to remodel the hand, and do it up in bandages or plaster. They are able, for a while at least, to delude some shallow wits into the belief that the joints are becoming smaller and the fingers more tapering, which seems to be the goal of hand-beauty, unless we recognize the demand of some for sharpened nails, a development that they can hardly expect to use either for offense, defense, or convenience; although I did know an individual who avowedly grew the left little finger-nail to special length for toilet uses, and the famous Lady Mary Whortley Montague, when reproached by a friend for her dirty nails, replied that she must scratch. In reality, nothing except protection from the effects of work in enlarging the joints or in roughening the skin will add to the existing symmetry of the individual hand, so that hand rest and the constant use of gloves will accomplish more than the most pretentious beautifier advertised in print or by reference.

As to the nails, one's own ordinary care in trimming and cleaning gives results fully equal in attractiveness to the *chef d'œuvres* of the manicure, whose tinting and waxing so interfere with the natural color-blending with the adjoining skin as to make the exhibit as unpleasing as the varnished hoofs of the Central Park hackney.

Since we have got so far in our subject it would seem incomplete did we not mention some of the methods not usually undertaken by others than licensed practitioners. There are many so-called depilatories on the market, all having as a base one of several substances similar to calcium sulphide (popularly unidentified except by its odor) which, when made into a paste with water and spread and allowed to remain on the offending hairy area for a minute or two, will destroy that part of the hairs above the skin surface. This, of course, requires repetition every few days, in fact oftener than the method of pulling the hairs out with a pair of tweezers, and is only better than the daily pumice-stone rub, to grind off the previous twenty-four hour's growth, or the regular shave. Possibly the regrowing hair is stronger than before, but it is more than probable that it is so in appearance only, as what was previously a part of the stump has been pushed out till it has become the tip, and the softening effect of the original taper has been lost. Of course after a time each hair would be worn to a point by friction, which is the natural cause of the original taper. There is great sale for many of these depilatory preparations, although, if one is not satisfied with the result of daily applications of peroxide of hydrogen, which bleaches even quite large hairs into comparative invisibility, the electric needle of an expert—actual, and not in name only, lest disaster be courted—had better be sought.

By this method, one sitting a week of an hour's length enables the operator to attack about fifty hairs by thrusting his little needle along each of their shafts, and then having the patient touch the other electrode, which, by a contact of about half a minute, causes destruction of the hairbulb or root—in those cases where the needle has accurately reached it—in about two-thirds of all careful attempts. Repeated sittings are of course required, and all failures necessitate a reattack. Of course all this is tedious, expensive, and somewhat painful, but there is no easier thorough way. The *x*-ray has been used, but is very dangerous, and usually the growth returns somewhat stronger than before.

Of course there are many congenital and accidental defects that may be remedied by plastic surgery, but the paraffin injection idea, popularly so well known, is not feasible, and I know of no one so reckless as to think of its employment.

Moles and warts on most of us who are not as ugly as Oliver Cromwell are such distinct detractions that it is surprising how many make pets of theirs, refusing even entreaties to allow a clip of the scissors, if not to make classical, at least to generalize their features.

While individual muscles may be enlarged by special exercise, local fat deposits cannot be influenced, except in common with the general padding of the entire body, notwithstanding all the gyrations and regimens, as ridiculous as the pretensions of those who recommend them, propounded by the professional beauty claimants of the day.

As a most horrible warning against the antifats of the advertisers, I quote the case of a 235-pound woman who told me to-day that she recently sent $25 to one of them for their "specific," but was so worried by the appearance of one of the capsules received, which was labeled "special," to be taken last, that she sent it to a laboratory for examination, and, I think, was permanently cured of her "reducing" mania when it was reported to contain the head of a tapeworm.

Many "antifats" have been found to contain thyroid-gland substance, and are fortunately rarely taken by anyone for a long period, as careless administration of this drug is thought to be dangerous, although in at least some cases, and to some degree, it is undoubtedly effective.

The foregoing covers at least most of the real cosmetic possibilities, though, of course, as analysis has so frequently disclosed, many of the advertised nostrums contain nothing pharmacodynamically effective, and sell on their label, their color, and their flavor, trusting for credit to what may be called the innate Christian Science of their purchasers.

140 Clinton Street.

## THREE IMPORTANT DON'TS IN BONE PLATING.

By G. P. COOPERNAIL, M.D.,

BEDFORD, N. Y.

1. Don't plate a compound fracture until the wound has healed and all danger of infection is past.

2. Don't plate a fracture that fails to unite where there is good apposition and no tissues between the ends of the bone. The plate will not help you get a good strong callus. Try injecting blood between the ends of the bone (Bier) or glycerite of tannin (Dawbarn).

3. Don't put your fingers in the wound if you *do* wear gloves, and it is better to boil the instruments after being used in the wound before using them the second time.

**Acute Osteomyelitis of the Upper Jaw.**—H. Fliess reports a case of this condition occurring in an infant three weeks old. The symptoms were as follows: swelling of the left molar region, edema of the eyelids, bulging of the hard palate and alveolar process, the escape of pus through an incision, the detection of exposed bone by means of a probe, and the escape of the rudiments of two molar teeth. The infant made an uneventful recovery.—*Archiv für Kinderheilkunde.*

**The Painful Symptoms of Poliomyelitis.**—E. Tezner states that these symptoms include the cutaneous hyperesthesia; the spontaneous pains in the affected limbs; the pains along the spine, particularly on motion; and the pains on pressure along the peripheral nerve trunks and over the muscles. To these is added by the author a fifth symptom, namely, the pains arising on active and passive motion, which causes a stretching of the larger peripheral nerves. These pains are detected among the initial symptoms and even as late as the second month of the disease.—*Monatsschrift für Kinderheilkunde.*

**Influence of Ions Upon the Action of Digitalis.**—A. J. Clark states that the action of digitoxin depends entirely upon the concentration of the drug, except when very small quantities of fluid are used. Digitoxin and strophanthin have no diastolic action upon a frog's heart perfused in the manner described by the author. When digitoxin and strophanthin act on the frog's heart only minute quantities are absorbed, but the quantity is not so minute as to exclude the possibility of chemical combination between the drug and the heart muscle. The systolic action of digitoxin upon the frog's heart is dependent upon the presence of calcium. Diminution in the quantity of calcium in the Ringer's fluid diminishes the systolic action of digitoxin. The presence of excess of alkali or the absence of potassium slightly increases the systolic action of digitoxin. The presence of excess of calcium or of blood serum, does not influence the systolic action of digitoxin.—*Proceedings of the Royal Society of Medicine.*

## DORSAL PERCUSSION IN THE DIAGNOSIS OF APPENDICITIS.

THE importance of making an early diagnosis in a case of appendicitis and the obscurity in the physical signs and symptoms that occasionally renders a diagnosis at any stage of the disease well nigh impossible, impart considerable importance to any new physical sign that may, if only to a slight degree, assist in the diagnosis. Such new physical sign is probably that which has been demonstrated in the method of dorsal percussion as practised by William Ewart (*British Medical Journal*, December 28, 1912). This observer, who within recent years has called attention to a number of the hidden possibilities of plessimetric percussion, notes that in normal individuals, over the posterior aspect of the sacrum and ilium, the percussion note is one of resonance. Between the sacral area and that covering the ilium there is a patch on each side, oblong in shape, lying at the junction of the sacrum and ilium, and corresponding to the crest of the posterior iliac tuberosity. This area may be easily mapped out with the aid of a Sansom's plessimeter. These two so-called "posterior iliac patches" present a note of subresonant dullness in contrast to the resonant note over the ilium and over the sacrum. The right patch is somewhat duller than the left. In cases of appendicitis the dullness is no longer confined to the right normal patch, but extends outward over the right iliac surface. In rare instances the dullness may extend over the surface of the sacrum.

The value of the dorsal method of percussion, according to Ewart, is revealed in the fact that there are acute cases of appendicitis without localizing physical signs in the abdomen. In these cases dorsal percussion almost invariably provides the characteristic evidence. Cases of retrocecal appendicitis, in which the abdominal signs are less apt to be in evidence, and particularly cases of retrocecal appendicular abscess, cannot escape observation if the dorsal method of percussion is employed. Cases of suspected appendicitis when subjected to the test of this method pass into the group of positive cases, as has been confirmed in a number of instances by the subsequent operation.

Transfixion experiments have shown that the normal right dorsal patch corresponds to the thick intestinal structures of the ileocecal junction, of the valve, and of the root of the appendix. Any pathological thickenings tend to intensify the dullness. Following an operation for appendicitis, providing the result is a perfectly clean one, the posterior right dorsal patch of dullness disappears entirely.

The dorsal method of percussion furnishes three diagnostic criteria. When the results of percussion are negative one may be assured of the absence of any inflammatory lesion in or about the appendix. If the method gives positive results then a suspicion that appendicitis exists is confirmed. It provides definite localizing evidences in a small group of cases with severe symptoms in which the lesions are deep-seated and consequently "latent."

It may be difficult for most observers whose ears are not adept in the discrimination of delicate shades of dullness, to avail themselves of this novel method of diagnosis. Nevertheless, the extraordinary claims made for the latter justify an extended employment of the dorsal method of percussion in all physical examinations, if only for the purpose of training the examiner to appreciate any differences, however slight, in the dorsal percussion note. Undoubtedly further extended trial will enable one more definitely to estimate the validity of the dorsal sign in the diagnosis of appendicitis.

## ATHLETICS IN GERMANY.

GERMANY has taken up athletics, not as a fad or craze, but as an institution for which the time is evidently ripe. Hitherto the place of athletics has been occupied by gymnastics, and the former is in no wise to displace the latter, for each is to represent an arm of the same service. It is conceded that gymnastics furnishes no element of enthusiasm. That such an adoption of national athletics is assured for the future well appears in the formation of a new society for the scientific study of sports which recently assembled for the first time (*Muenchener medizinische Wochenschrift*, December 3). The membership appears to be limited to medical men. Of a large number of papers read, there were several on athletic heart, which, according to Kraus of Berlin, is very largely an affection of the right heart. Though to a certain degree physiological, it often represents a lesion. Electrocardiograms of great value have been obtained which characterize a threefold condition—"youth, health, and the state of training." Data concerning physiological hypertrophy have been collected which show a distinct relationship between relative size of heart and relative activity. The stag has the largest heart and the phlegmatic domestic pig the smallest. Wild animals have larger hearts than their domestic representatives. Next to the athletic heart, athletics for women seems to be the most vital topic and one member seeks to explode the heresy that housework for women is able to replace athletics and gymnastics. Swimming, rowing, golf, and tennis are suited to women, while for a steady diet, walking and gymnastics should be depended upon. One author believes that girls should not take up athletics until after puberty. One day's rest just before menstruation is imperative.

Among the recommendations made were the following: Olympic competitions should be international, not merely national; six-day contests should not be tolerated; there should be an Imperial Commission for the supervision of all exercises; the wholesale athletic awakening will tend to develop new instruments and methods for anthropometry; and finally of great economic value are the winter sports which take people out of doors when their natural disposition would be to become more sedentary.

## NEPHRITIS FOLLOWING TONSILLITIS.

Idiopathic nephritis, whether acute or chronic, has always presented an added element of mystery when contrasted with idiopathic inflammation of certain other organs. Young subjects in the apparent prime of vigor and in the absence of any causal nexus, such as is usually necessary for the development of affections of this kind, are stricken down and either perish in a short time or become hopeless invalids. The questions most frequently asked under the circumstances have reference to the impossibility of foreseeing and preventing the lesions. Certain remote factors are grasped at which are, perhaps, not at all concerned in the etiology. We must assume that the organs represented a weak point in the economy and perhaps had been damaged by scarlatina in early childhood. Or investigation may show a familial tendency to nephritis. For corresponding exciting factors we have recourse to hypothetical toxins, exogenous or endogenous, such as are abundantly evident in secondary nephritis.

It is plain that any positive association of an idiopathic nephritis with any causal factor whatever, however slight this may be, may be made to throw reflected light on the entire question of etiology. At a medical meeting during the present year (*Münchener medizinische Wochenschrift,* No. 50, p. 2764) Geiger reports a series of cases in young subjects, from 12 to 25 years of age, who with year-long tendency to ordinary lacunar tonsillitis finally developed attacks of acute nephritis in immediate sequence to acute anginas. One patient was dead of uremia at the end of three weeks, while the others came off easily. Such cases are by no means rare. In the absence of elaborate studies we do not know how the kidney lesions originate, but the supposition of a so-called septic rheumatoid infection is not unwarranted. Much of the nephritis in scarlatina doubtless originates in a similar fashion.

The lesson to be derived from such cases, if any is needed, is the necessity of extirpating chronically infected tonsils. From analogy we might expect that other cases may occasionally arise from intranasal and sinus disease.

## The Relative Importance of Aerial and Contact Infection.

In a paper read before the International Congress of Hygiene and Demography, held at Washington last September, Dr. Charles V. Chapin called attention to the diminishing belief in the importance of infection by means of contaminated air. Formerly it was thought that yellow fever, influenza, cholera, scarlet fever, typhoid fever, smallpox, diphtheria, and tuberculosis were all air-borne diseases. Experiments establishing the insect origin of yellow fever and malaria have proven that at least these two diseases are not in the air-borne group. There is no good evidence of the air carriage of typhoid fever or cholera and the rapid diffusion of influenza can be explained by the ubiquity of carriers. Observations around hospitals and dwellings show that diphtheria and scarlet fever are not carried by the outer air and the consensus of opinion of the bacteriologists is that tuberculosis is probably not transmitted in this way. The view of certain English observers that smallpox may be carried long distances through the medium of air alone has not stood the test of careful analysis. The existence of carriers and mixed cases affords such ample opportunity for infection by contact that the theory of aerial transmission is no longer required to explain the origin of hitherto unexplainable cases of contagious diseases. However, it is theoretically possible that the contaminated air of houses and hospital wards may transfer the disease from one part of the infected building to another, although the virus may be too diluted in the outer air to do any harm. But even in the case of indoor infection the evidence for air transmission is not strong. The bubonic type of plague, Mediterranean fever, cerebrospinal meningitis, and poliomyelitis do not spread in hospital wards. When hospital infection occurs in cholera and typhoid fever it can invariably be traced to a contact infection. Typhus fever is transferred by insects, and the experience of Mexico and England with this disease shows that infection by air does not occur in hospital. By a study of conditions in Providence, Chapin found that scarlet fever and diphtheria are not air-borne from family to family in the same dwelling. An identical opinion has been reached by independent observers in other parts of the United States as well as in France and England. Finally it would seem that it has been definitely proven that air is practically a negligible factor in the transmission of all the contagious diseases except measles, whooping-cough, smallpox, chickenpox, and rubella. In regard to these opinion is still divided.

## Alcoholism and Tuberculosis.

Within the memory of most of us alcohol was considered the natural enemy of tuberculosis. A barrel of whiskey, a barrel of cod liver oil, and a life on the open plain was an old fashioned cure for consumption. But the evidence accumulates that the advocates of alcohol were mistaken in their views. In a recent paper Dr. Jacques Bertillon, Chief of the Bureau of Municipal Statistics in Paris, gave it as his opinion that alcohol may be called the principle cause of phthisis. In support of this contention he cites the mortality statistics of 100,000 men of all ages (England, 1900-02), which show the death rate from phthisis to be twice as great among innkeepers as among shopkeepers. Innkeepers he considers to be professional alcoholics, whereas other shopkeepers are not: *ergo,* alcohol causes the phthisis in England! Again he says that all France is divided in two sections—that north of the river Loire where the grape vine does not thrive and where the favorite beverages are cider and beer. There much alcohol is consumed and phthisis is of very frequent occurrence. The other section of France is south of the Loire and

here the grape thrives and the principal beverage is claret. Here phthisis is of rare occurrence. So he considers that in France the distribution of phthisis bears an inverse relation to the prevalence of light wine drinking habits as contrasted with the custom of imbibing the stronger alcoholic beverages. While the argument in the particular instance seems to be a little far fetched, the general principle is fairly universally now admitted that tuberculosis in common with all other diseases develops most rapidly in those whose constitutions are weakened by excessive indulgence in alcoholic beverages.

### Hospital Noise.

The importance of maintaining quiet in the wards and halls of the hospital is so obvious that one may be surprised that any comment upon it nowadays is at all necessary. Yet there is no hospital in which the ideal of quiet is attained. Apart from the unavoidable noise emanating from the patients themselves there are a large number of sources of noise that may be effectively controlled. Not sufficient effort is made to enforce upon the medical and nursing staff the importance of carrying on all conversation in a whisper, of moving noiselessly through the wards and other parts of the hospital building, and of supervising the removal of patients as from the wards to the operating room, or vice versa, in such manner that the least amount of noise is created. There is no reason why the same quiet that is maintained in the reading rooms of public libraries should not also be observed in the hospital. The harsh ring of the electric bell is one of the constant sources of annoyance to patients. The substitution of the buzz for the ring, or even the entire elimination of the bell by the introduction of a system of flash signals, would be a vast improvement over the present system.

## News of the Week.

**To Revise Health Laws.**—Governor Sulzer of New York recently announced the appointment of a commission of eight persons who will make an investigation of the health conditions in this State, with the view of recommending changes in the public health law and methods by which epidemics of disease prevalent in some portions of the State may be stamped out. The commission will also probably be called upon to advise the Governor in the selection of a State Commissioner of Health to succeed Dr. Eugene H. Porter, whose term of office expired on January 1. The members of the commission are Dr. Hermann M. Biggs, New York, chairman; Mr. Homer Folks, New York, secretary; Mr. John Kingsbury, Yonkers, assistant secretary; Dr. Edward R. Baldwin, Saranac Lake; Mr. Ansley Wilcox, Buffalo; Miss Adelaide Nutting, New York; Dr. John C. Otis, Poughkeepsie, and Dr. W. E. Milbank, Albany. The Governor quotes the statistics of 1911, which show that during that year there were in the State a total of 145,338 deaths, of which 14,179 were due to pulmonary tuberculosis and 1,310 to typhoid fever, as proof that the health laws require change. The recommendations of the committee will be transmitted to the Legislature by the Governor in a special message.

**The Board of Food and Drug Inspection.**—Willard D. Bigelow, Ph. D., has been appointed a member of the board of food and drug inspection, filling the vacancy on the board caused by the retirement of R. E. Doolittle, the recent acting chief of the bureau. The other members of the board are Dr. Carl L. Alsberg, chairman, and A. S. Mitchell, formerly chief of the St. Paul food and drug laboratory. The board of food and drug inspection has the function of weighing the evidence presented against foods and drugs collected by inspectors and investigators of the bureau, and of considering the arguments of the manufacturer.

**Immigration of Insane and Defectives.**—The following resolutions regarding the exclusion of insane and mentally defective immigrants have been sent to the Hon. Henry Cabot Lodge, chairman of the Senate Committee on Immigration, and to the Hon. John L. Burnett, chairman of the House Committee on Immigration and Naturalization, by the members of a conference of alienists and social workers which met in New York City on November 16, 1912. After several preambles rehearsing the evils resulting from the admission of insane immigrants it was resolved that the members of the conference urge upon Congress the necessity of providing facilities for the adequate examination of immigrants for mental diseases and defects, and also urge the enactment of the following amendments to the present immigration laws: (1) A provision making it an offense, punishable by a fine of not less than $100, for transportation companies to bring to this country any insane or mentally defective immigrants, whose condition could have been detected by a competent medical examination at the time of foreign embarkation. (2) A provision authorizing the detail of commissioned medical officers of the United States Public Health Service to any vessels bringing immigrants to the United States, such medical officers being required to examine immigrants, with special reference to their mental condition, on the voyage to this country, and being empowered to see that the provisions of the "passenger act," which apply to the care and to the safety of immigrants at sea, are enforced. (3) A provision requiring that a sufficient number of commissioned medical officers of the United States Public Health Service, with especial training and experience in the detection of insanity and mental defectiveness, shall be detailed for duty at Ellis Island at all times, and that at least one such medical officer shall be detailed at every other large port of entry. (4) A provision requiring that medical officers engaged in the mental examination of immigrants shall be provided at all times with the necessary facilities for the detention and examination of immigrants, including the exclusive services of interpreters. (5) A provision requiring that insane or mentally defective aliens, who gain admission to the United States in violation of law, or who become a public charge within five years, shall be deported, unless it is shown that their mental disease or defect was due to causes arising subsequent to their landing in this country. (6) A provision requiring that suitable attendants of the same sex shall accompany insane or mentally defective aliens who are being deported from this country in all cases in which it is certified by a medical officer of the United States Public Health Service or by the chief medical officer of an institution in which such aliens are confined that their mental or physical condition is such as to require personal care and attendance, and also requiring that the attendance provided shall be for the final destination of each such alient deported. It was further resolved that the members of the conference express themselves in favor of

any measures which will make it possible to conduct a medical examination of immigrants at ports of foreign embarkation.

**Need for Surgical Instruments.**—The American Board of Commissioners for Foreign Missions, which conducts extensive medical work in Turkey, India, China, Africa, and the Islands of the Far East, appeals to the surgeons of the United States for their discarded but serviceable surgical instruments. Instruments of this sort, never used because they have been displaced by more modern forms, are in the possession of almost every practitioner, and would be of immeasurable value to those physicians who are out beyond the frontiers of civilization, striving under most hampering conditions to meet the medical and surgical needs of people who would otherwise have no modern aid whatever. If given to the American Board such instruments would at once be sent to places where the need is greatest and would be put into immediate service. They would be gladly received for distribution by any of the following: John G. Hosmer, 14 Beacon street, Boston; Edward Lincoln Smith, D. D., Fourth avenue and Twenty-second street, New York; A. N. Hitchcock, D. D., 19 South LaSalle street, Chicago; H. M. Tenney, D. D., Mechanics' Bank Building, San Francisco.

**Russian Dentists Jailed.**—An interesting trial involving fraud in connection with the obtaining of dentists' certificates in Moscow, Russia, was concluded recently with the sentencing of a number of Jewish dentists to spend a year each in prison. Until a short time ago the Jews in Moscow were allowed to practise dentistry after serving an apprenticeship, various other much coveted privileges also being granted to the dentists, but this procedure was abandoned and a diploma from the University of Moscow was made a requirement for a license. A fraudulent scheme was then inaugurated by which the Jews could obtain certificates dated back before the holding of a diploma was made necessary, and the uncovering of this fraud resulted in the arrest of over five hundred persons and the final conviction of two hundred and one dentists and nine physicians and officials who had aided in the scheme.

**Riot over Doctor.**—In the village of Roccagorga near Rome, Italy, two persons were killed and four wounded in a riot on January 6, following a demonstration in the town against a physician who was accused of neglecting his poor patients in favor of those who would pay him large fees. Such conduct, evidently regarded by the simple villagers as most unusual and improper, caused bitter feeling, and a parade of protest was organized. A clash between the paraders and the soldiers followed with fatal results. In the midst of the excitement the population of the town was decreased by the quiet departure of the physician.

**Mary Putnam Jacobi Fellowship.** — The Women's Medical Association of New York City offers the Mary Putnam Jacobi Fellowship of $800 available for post-graduate study, which is open to any woman graduate of medicine and is awarded upon proof of ability and promise of success in the chosen line of work, not upon competitive examination. Applications for the next award, which will be made on June 1, to cover the year from October 1, 1913, to October 1, 1914, must be in the hands of the committee by the first of next April and must be accompanied by testimonials as to the health, ability, character, and educational qualifications of the applicant, as well as a statement of the work in which she proposes to engage and of work she has already done. All communications may be addressed to Dr. Emily Lewi, chairman, 35 Mt. Morris Park W., New York.

**Congress for Physiotherapy.**—The Fourth International Congress for Physiotherapy will be held in Berlin from March 26 to 30, 1913, under the protection of Prince August Wilhelm of Prussia and the presidency of Prof. Dr. His and of Prof. Dr. Brieger of Berlin. The work of the congress will be conducted under four heads: I. Hydrotherapy, thallassotherapy, balneotherapy, and climatotherapy. II. Electrotherapy and radiotherapy. III. Kinesitherapy. IV. Diathetics. American physicians proposing to attend the congress should communicate promptly with the chairman of the American members of the Permanent Committee, Dr. G. Betton Massey, 903 Professional Building, Philadelphia.

**Information Regarding Clinics.**—A Bureau of Information has been opened at the New York Academy of Medicine, under the direction of The Society for the Advancement of Clinical Study in New York, the object of which is to furnish to visitors and to the local profession information on medical subjects, so as to make use of the large clinical opportunities that are always here. Medical men of New York and Brooklyn are requested to furnish the bureau with information regarding such of their clinical work as they are willing any physician should see. Information as to autopsies, laboratory demonstrations, lectures, medical clinics, and operations is desired. An attendant in charge of the bureau will be at the Academy daily after nine o'clock, for the express purpose of receiving all information, and promptly posting the same on a special bulletin board. The attendant is ready to give every assistance in furnishing information.

**City Deaths.**—For the week ending January 4, the deaths in New York City numbered 1,519, an increase of 114 as compared with the same week a year ago.

**Low Death Rate.**—East Orange, N. J., which has enjoyed the distinction of being the healthiest town in the United States, has taken another point off its annual death rate, bringing it down to 8.21.

**Infant Death Rate.**—During the year 1912, the infant mortality in New York City decreased 6 per cent., the total number of deaths being 14,289 as compared with 15,053 in 1911. At the same time the number of births increased by 1,081.

**Personals.**—Dr Archibald L. Muirhead, professor of physiology and pharmacology in the John A. Creighton Medical College of Omaha, Neb., has recently been appointed dean of the college to succeed Dr. Dewitt C. Bryant, resigned.

On January 11, the Senate confirmed the nomination of Brigadier-General George H. Torney to be Surgeon-General of the United States Army.

**Surgeon Held Liable.**—In the Supreme Court of New York on January 10, damages amounting to $11,700 were awarded by a jury to a woman patient who had sued a physician of Old Westbury, charging unskilful treatment for a fracture of the leg. The plaintiff was treated for injuries received in an automobile accident, and she contended that the failure to use the *x*-rays and to place the fractured bones properly were acts of negligence for which the physician was responsible.

**Northern Medical Society.**—A meeting of this Society will be held at 12 Mt. Morris Park West,

New York, on Monday, January 20, 8.45 P. M., at which the following papers will be read: Dr. Alexander Goldman, "A Plea for Early Operation in Abdominal Cases"; Dr. A. L. Soresi, "Unsatisfactory Coitus as a Cause of Neurasthenia and Other Disorders in Women." All members of the profession are cordially invited to attend.

**American Institute of Homeopathy.**—The next convention of this organization will be held in Denver, Col., in July, 1913.

**The New York Psychiatrical Society.**—At a recent meeting of this society the following officers were elected to serve during the ensuing year: *President,* Dr. Charles L. Dana; *Vice-President,* Dr. William L. Russell; *Secretary and Treasurer,* Dr. Swepson J. Brooks.

**Obituary Notes.**—Dr. Willard Ide Pierce of New York, professor of materia medica in the New York Homeopathic Medical College and Hospital, New York, from which institution he was graduated in 1891, a member of the American Institute of Homeopathy, the New York State Homeopathic Medical Society, and the New York Academy of Pathological Science, and for many years attending physician at the Flower Hospital, died at his home on January 8, aged 56 years.

Dr. Herbert W. Morehouse of Danville, Ill., a graduate of Rush Medical College, Chicago, in 1870, a member of the American Medical Association and of the Illinois State and Vermilion County Medical Societies, and for twenty-one years chief surgeon of the Wabash Railroad, died at his home of cancer of the esophagus, on December 21, aged 68 years.

Dr. Robert Young Rudicil of Trion, Ga., a graduate of the Medical College of the State of South Carolina, Charleston, in 1855, died at his home from pneumonia, on December 24, aged 80 years.

Dr. John Guerin of Chicago, Ill., a graduate of the Rush Medical College, Chicago, in 1866, and a member of the American Medical Association and the Illinois State and Cook County Medical Societies, and of the Board of Education of Chicago, died suddenly on a train near Memphis, Tenn., on January 2. Dr. Guerin had been in poor health for some time and was journeying to the South in the hope of receiving benefit.

Dr. L. Haines Crothers of Chester, Pa., a graduate of the University of Pennsylvania, Department of Medicine, in 1899, and formerly a member of the surgical staff of the Chester Hospital, died at his home on January 2, aged 36 years.

Dr. John A. Burlington of Duryea, Pa., a graduate of the Baltimore Medical College in 1890, and a member of the Pennsylvania State and Luzerne County Medical Societies, died at his home on January 2, aged 55 years.

Dr. William Patch of Coleta, Ill., a graduate of the Western Reserve University, Medical Department, Cleveland, Ohio, in 1885, and a member of the American Medical Association and the Illinois State and Whiteside County Medical Societies, died in the Watertown State Hospital on December 26.

Dr. William M. Gross of Gillespie, Ill., a graduate of the College of Physicians and Surgeons, Keokuk, Iowa, in 1875, and a member of the Illinois State and Macoupin County Medical Societies, died at his home, on December 18, aged 70 years.

Dr. Ralph F. Sommerkamp of Philadelphia, Pa., a graduate of the Medico-Chirurgical College of Philadelphia in 1899, and a member of the Pennsylvania State and Philadelphia County Medical Societies and of the American Medical Association, died at his home, on December 23, aged 47 years.

Dr. Robert Bradler Welton of Brooklyn, N. Y., a graduate of the Harvard Medical School, Boston, in 1868, and a member of the New York State and Kings County Medical Societies and the Brooklyn Pathological Society, died at his home on January 7, aged 69 years.

Dr. Keran O'Brien of Brooklyn, N. Y., a graduate of the Long Island College Hospital, Brooklyn, in 1901, and a member of the New York State and Kings County Medical Societies, died at his home on January 6.

Dr. Royston Ford of Greenville, O., a graduate of the Cincinnati College of Medicine and Surgery in 1880, while in his automobile crossing the tracks of the Pittsburg-St. Louis Railroad, was struck by a freight train and instantly killed, on January 3, aged 66 years.

Dr. Robert Eddy Bell of Lowell, Mass., a graduate of the New York Medical College in 1883, a member of the American Medical Association and of the Massachusetts State and Middlesex County Medical Societies, and a volunteer surgeon in the United States Army during the Spanish War, died at his home on January 4, aged 52 years.

Dr. Edgar C. Syrett of West Springfield, Mass., a graduate of the University of Vermont College of Medicine, Burlington, in 1898, and chairman of the West Springfield Board of Health, died at his home on January 5, aged 40 years.

Dr. Waine Sims of Crosskeys, Ga., a graduate of the Reform Medical College of Georgia, Macon, in 1857, died at his home on January 3, aged 83 years.

Dr. Ben Kissinger Clifford of Denver, Col., a graduate of the Denver and Gross College of Medicine, Denver, in 1909, died at his home from Bright's disease, on December 29, aged 27 years.

Dr. N. G. Mothershead of Earlington, Ky., a graduate of the Hospital College of Medicine, Louisville, in 1879, died suddenly at his home on December 30, aged 68 years.

Dr. James H. Owsley, retired, of Sonora, Ky., died at his home after a short illness, on December 28, aged 74 years.

Dr. Thomas Spec Jones of Baton Rouge, La., a graduate of the Pennsylvania Medical College, Gettysburg, in 1848, died suddenly at his home on December 31, aged 85 years.

Dr. James Bosley of Baltimore, Md., a graduate of the University of Virginia, Department of Medicine, Charlottesville, in 1874, a member of the American Medical Association, the Maryland State and Baltimore City Medical Societies, and the Maryland Psychiatric Society, and Commissioner of Health of the City of Baltimore, died at his home after a short illness on January 5.

Dr. A. T. Henton of Bloomington, Ill., died at his home on January 6, aged 64 years.

Dr. Franklin G. Humiston of East Jaffrey, N. H., a graduate of the University of Pennsylvania, Department of Medicine, in 1886, and a member of the New Hampshire State and Cheshire County Medical Societies, died at the Eliot Hospital, Boston, on December 30, aged 57 years.

Mr. Ewen McIntyre, said to be the oldest pharmacist in New York City and the oldest living graduate of the College of Pharmacy, of which he was for many years president, died at his home on January 9, aged 88 years.

# Correspondence.

## INFLATION OF STATISTICS.

To the Editor of the Medical Record:

Sir:—I have read the letter in your journal of January 11 by Dr. Herman B. Sheffield, complaining of the "Inflation of Statistics" as emphasized by a recent publication of mine on Primary Splenomegaly. The facts are so inconsistent with his contentions that I feel constrained to lay them before you.

On November 4, 1911, Dr. Sheffield recorded two cases in the Medical Record under the caption of "Primary Splenohepatomegaly in Brother and Sister." Until the last paragraph is reached there is no suggestion in the article that these cases may belong to the group of Primary Splenomegaly as described by Gaucher. Indeed, Dr. Sheffield closes his article, after having received an intimation from an eminent consultant as to the nature of the disease, as follows: "Disappointed in the diagnosis as well as treatment, I directed the mother to go with the child to the country."

So, as far as the literature is concerned, Dr. Sheffield's report adds no case to the small list of those which have been recorded and proven. This same case was, however, recognized and described by Dr. Mark S. Reuben as a case of "Splenomegaly (Gaucher)," in the *American Journal of Diseases of Children*, January, 1912. The patient subsequently was admitted to Mount Sinai Hospital, was operated upon by Dr. J. Wiener, died, and an autopsy was performed at the hospital, definitely establishing the diagnosis anatomically and histologically.

Reference to my article in *The Journal of Experimental Medicine*, Vol. XVI, No. 6, will show that I have included in my report, which represents entirely a pathological study of the disease, only such cases as have been shown anatomically to belong to the Gaucher type. A perusal of Dr. Sheffield's report discloses that Dr. Flexner called his attention to a previous paper by Drs. Brill, Mandlebaum, and Libman, and in referring to this fact, he states that our cases "bear a close resemblance to those under consideration." This is the only reference in Dr. Sheffield's report to the Gaucher type of splenomegaly. For obvious reasons, therefore, no reference was made to his report, though I was thoroughly familiar with it.

It is, however, solely in a scientific interest that I write to you. Far from desiring to "inflate statistics" my desire to do the reverse is specifically stated in my paper now under criticism by Dr. Sheffield. This particular case is now recorded in literature as primary splenomegaly of the Gaucher type but *once*, clinically by Dr. Reuben, anatomically by me. And I have credited Dr. Reuben with the case because he distinctly and specifically described it as a case of Splenomegaly (Gaucher).

F. S. Mandlebaum, M.D.

New York.

---

## OUR LONDON LETTER.

(From Our Regular Correspondent.)

INSURANCE—DISSENTIENTS—INTESTINAL STASIS—TROPICAL EXPEDITION—KING EDWARD'S HOSPITAL FUND—OBITUARY.

London, Dec. 27, 1912.

Christmas week brings no peace and good will in the profession. As far as the insurance question is concerned, the dissension is acute, and Mr. Lloyd George may plume himself on having divided his opponents. The voting conducted by the B. M. A. showed an overwhelming majority for refusing to work the Act, but the minority broke away, organized itself, and is ready to take service under the State. The socialists are, of course, delighted, and their organs in the public press are repeating abuse and insult on the profession which hesitates to sell its independence. So-called liberal papers are following the lead of the extremists, although they can scarcely help seeing that it is in direct contradiction to their traditional policy of individual freedom. The B. M. A. is now committed to a scheme of its own which will ensure freedom for both the profession and the public and can be worked by local committees. But the government is forming its panels in some places and making great efforts to do so in others. Where they fail they declare they will adopt other means to give medical attendance to insured persons, and they have no doubt they can get whole-time doctors to fill their panels and threaten to introduce such practitioners, allowing them also to compete for private practice. Such is the spirit with which the fight is to be fought. In some places the panels are already practically filled; in others there seems little chance of this being done—certainly for some time—but with an active hostile minority it is not easy to forecast the probable end, which begins to look like a reorganization of the profession being accomplished. The B. M. A. made a mistake in consenting to a conference with the chancellor. It was certain that the deputation could not deal with so domineering a man, who had the power of the sovereign behind him as well as long experience in confusing issues in various controversies.

"Chronic Intestinal Stasis" was the title of a paper read by Mr. Arbuthnot Lane at the Medical Society of London, and which led to an interesting discussion extending over two evenings. Mr. Lane included in the tour any abnormal delay in the passage of the intestinal contents through any part of the gastrointestinal tract which results in the absorption of toxic materials in greater quantity than can be treated effectually by the organs whose function it is to convert them into products as innocuous as possible to the body tissues. Excess of these products, as of the poisons themselves, sets up changes in all the tissues—probably most of all in those organs whose business it is to convert or eliminate them, say the liver for conversion and the kidneys and skin for elimination. But the part taken by the thyroid, pituitary body, and the suprarenals may prove to be more important than our present information indicates. Operations on the drainage scheme have demonstrated the damage done by these poisons and the remarkable power of repair the tissues show when freed from them. Mr. Lane referred to Carrel's magnificent work, which shows the wisdom of attending to the drainage scheme of the body, and presents points of interest as to the growth of malignant disease. He holds that intestinal stasis results in autointoxication, which inhibits the capacity of the tissues to resist the entry of organisms such as those of tubercle and rheumatoid arthritis. So he adopts means to improve the drainage system, either mechanical or operative, and he reports excellent results—such as rapid disappearance of tubercular glandular masses from the abdomen after disconnection of the large bowel. Cases of pigmentation of the skin diagnosed

as Addison's disease by competent physicians have been rapidly restored in the same way. Bright's disease, cancer of the breast, or liver, or pancreas, he seems to regard as the products of the toxins of the stasis. The influence on the nervous system must naturally be very great, and he cited typical cases. Adenoma of the thyroid and exophthalmic goiter associated with symptoms of intestinal stasis had disappeared rapidly after removal of the large bowel. The site of absorption is not only the lower bowel, as too many have supposed since Metchnikoff said we should live longer if we had not one, which saying Mr. Lane said was tried, as evidenced by the improved health following its removal. But, he added, this does not show the chief absorption is from the colon; on the contrary, he places the bulk of it in the small intestine, but here it is secondary to that in the large. If the cecum did not become overloaded, the obstruction at the ileum would not occur, the contents would not get infected, and the other sequelæ follow. The extraordinary improvement which follows short-circuiting, or disconnection or removal of the lower bowel, is due largely to facilitation of the escape from the small intestine of its infected contents and of organisms which only grow in stagnant material. Mr. Lane said he had just returned from the United States, where he had found the subject was dealt with in a practical manner by the most progressive surgeons in the world.

Mr. H. G. Plummer related his experience of the post-mortem appearances in animals. In enteritis suppuration of the germs was always present or he regarded it as a cause. He found no relationship between cancer and obstruction or constipation. Dr. A. C. Jordan showed a number of lantern slides illustrating the relation between the duodenum and ileum in such cases of stasis as congestion, ulceration, and cicatrization of the duodenum; also the simple stasis of ileum, or that with a kink setting up the obstruction, or that set up by the appendix, and further, one showing the upright posture in the presence of such kink might cause obstruction. He found the duodenum the most sensitive part. A characteristic writhing of it was often seen by *x*-rays, with great difficulty in the passage through it of a bismuth meal. Liquid paraffin had abolished stasis in some cases for a time; so had rest in bed, as also in dilatation of the stomach. In both cases there was hypertrophy from undue effort to force the contents forward.

Dr. Carson said great advances had followed the use of *x*-rays and bismuth meals. It was difficult to distinguish kinks of ileum from appendicitis. In operations full exposure of the parts likely to be involved should be made. Mr. H. H. Sampson said at St. Peter's Hospital bacilluria was so often seen with signs of intestinal stasis that he regarded this as a prime factor, and he related good successes in intractable cases with subacute exacerbations, not that the stasis was the only cause, for pyelitis was often an underlying condition. Dr. Leslie, at first skeptical, became a convert to Mr. Lane's views six years ago as the result of a case of twelve years' duration, sinking rapidly, for whom he advised trial of the operation by Mr. Lane, which being done, recovery took place at once. Many cases since with *x*-ray proofs satisfy him that the operation will become universally accepted. Mr. P. Daniel did not think the bands found primary causes, but infection and reinfection of the gastrointestinal tract, and the effects described by Mr. Lane, might occur apart from stasis. If infection were got rid of the stasis would disappear. He differed also as to treatment, especially for arthritic cases, and behind that the case for stasis remained improved. Dr. F. J. Smith could not think mammary cancer due to intestinal stasis, nor even pyorrhea alveolaris. Adhesions were common in the post-mortem room, too common to be the cause of symptoms demanding operation. Dr. Jordan's radiograms must be compared with an equal number from normal persons. In some cases with toxemia and all usual treatment failed, appendicostomy might suffice.

Dr. E. B. Ward said in children delay was more harmful in the small than in the large bowel. In advanced tubercular arthritis he had seen short-circuiting effectual. One case of rheumatoid arthritis had been greatly benefited. In severe chronic constipation, intractable to both drugs and diet, the operation was not risky, and mostly effectual. Dr. von Ofenheim commented on the antagonism between the different groups of organisms met with in the bowels. He thought treatment should be based on that, but unfortunately we do not yet possess sufficient knowledge of these organisms. Nor are we able to acclimatize the beneficial strains of bacteria.

The Liverpool School of Tropical Medicine has despatched its thirtieth expedition. This, under Dr. Seidelin, goes to Jamaica. It is the second expedition of the school to that island, and has been promised cordial support by the king's government, as well as by that of Jamaica.

King Edward's Hospital Fund has experienced its first check in the steady rise of its amount for distribution, due to a fall in the income of £50,000. To meet the case a sum has been drawn from former fat years' accumulation—a method of making both ends meet which cannot go on.

Dr. Peter Redfern, M.D., (Lond.), F.R.C.S.E., D.Sc., formerly Regius Professor of Anatomy and Physiology of Queen's College, Belfast, died on December 22, aged ninety-one. He wrote on the nutrition of articular cartilages in 1850, and as late as 1897 on the development of bone and cartilage in the *Journal of Anatomy and Physiology*.

Dr. Siordet, M.D. (Lond.), F.R.C.P. (Lond.), died at Mentone, where he practised many years, on December 22, in his eighty-fourth year.

## OUR LETTER FROM CUBA.

(From Our Regular Correspondent.)

CUBAN ASSOCIATION OF OPHTHALMOLOGY AND OTO-LARYNGOLOGY—BREAKFAST FOR SCHOOL CHILDREN—MONUMENT TO THE LATE DR. RIJO—CUBAN ASSOCIATION OF THE MEDICAL PRESS—THIRD CUBAN MEDICAL CONGRESS—MEDICAL MEN IN CONGRESS.

HAVANA, December 31, 1912.

THE Association of Ophthalmology and Oto-Laryngology of Cuba celebrated its second anniversary with a banquet at the "Carabanchel" on Dec. 29, the same being well attended. This medical society recently held its election of officers for the next year, with the following results: *President*, Dr. Emilio Martinez, Professor of Diseases of Ear, Nose and Throat in Havana; *Vice-President*, Dr. C. E. Finlay, Professor of Ophthalmology, Havana University; *Secretary*, Dr. J. M. Penichot; *Vice-Secretary*, Dr. E. R. Arrelano.

A wide and enthusiastic movement has been started in order to provide free breakfasts for poor

school children. About a thousand dollars has been obtained in the first week, and the *Figaro,* a well-known review, has offered to pay the expenses of one day each month. The problem is a big one, but it is hoped to obtain sufficient funds in order to give free breakfasts to all poor school children over the island.

The Cuban Association of the Medical Press has been recently formed through the cordial cooperation of all medical journalists in this city. The following officers have been elected for 1913: *President,* Dr. Juan Santos-Fernandez; *Vice-Presidents,* Drs. J. A. Presne and E. Nuñez; *Secretary,* Dr. J. F. Arteaga; *Vice-Secretary,* Dr. L. J. Cañizares; *Treasurer,* Dr. A. Gonzales Curquejo; *Vice-Treasurer,* Dr. Oscar Jaime. The association has a membership of over sixty.

In the city of Sancti-Spiritus the Municipal Council has voted a fund of $500 to open a public subscription in order to erect a monument to Dr. Rudesindo García Rijo, a famous philanthropist and medical man of that city, who was assassinated in his country home some months ago. Dr. García Rijo was a much beloved general practitioner and was very well known in our leading medical and social circles.

The third Cuban National Medical Congress, which will be held in the autumn of 1914, is about to commence its work. The Executive Committee is composed of the following officers: *President,* Dr. Gabriel Casuso; Dean of the Faculty of Medicine, Havana University; *Vice-Presidents,* Drs. F. Mendez Capote, J. Ortiz, José Guell, R. García Rijo, F. Sirven, and M. Weiss; *General Secretary,* Dr. Francisco M. Fernández; *Vice-Secretaries,* Drs. R. Nogueiras, A. Barreras, R. Perez Vento, and José de Cubas; *Treasurer,* Dr. G. Fernandez Abreu.

Several medical men have been recently elected to serve in the National Congress, and among them are the following: Pinar del Rio Province, Dr. A. Cabada and Dr. M. Gomez Rubie; Havana Province, Dr. Carlos Guas, Dr. Cecilio Acosta, and Dr. E. Porto; Matanzas Province, Dr. Francisco M. Fernandez; Las Villas Province, Dr. J. Mulkay, Dr. A. Calleja, Dr. Carlos Mendieta; Camaguey Province, Dr. J. R. Xiques, Dr. A. Hernandez, and Dr. Castillo; Oriente Province, Dr. J. Manduley. To the Senate have been elected Dr. E. Sanches Agramonte from Camaguey and Dr. Rubio from Pinar del Rio. Besides, Dr. Alfredo Carnot, a dentist, and Dr. A. Figueroa, a pharmacist, have also been elected to the Senate from Matanzas and Las Villas respectively, and Dr. J. Castillo, also a Doctor in Pharmacy from Camaguey, to the House of Representatives. With this large number of medical men in the Congress—about 20 per cent. of the total—measures of health and hygiene ought to receive respectful attention.

## OXIDATION IN CANCER.

To the Editor of the Medical Record:

Sir: Drs. Leo Loeb, McClurg, and Sweet publish in the *Interstate Medical Journal* the treatment of cancer by colloidal copper, thus producing fever or oxidation. Now, in the *Medical Council,* May, 1912, I stated any substance that would produce oxidation but not destroy normal tissue would overcome cancer. The above gentlemen have the same idea, and have proven my theory correct. (As a coincidence, they began the treatment of human cancer in May, 1912.) My formula is

℞

| | |
|---|---|
| Sod. chloridi | 2.00 |
| Pot. sulphatis | 0.070 |
| Sod. sulphatis | 0.063 |
| Cal. phos. | 0.075 |
| Magnesii phos. | 0.055 |
| Hemoglobin | 3.25 |
| Aquæ bullient. | 250. c.c. |

Dissolve the NaCl in boiling water, filtering when cool; add rest of salts and hemoglobin. This dose by mouth an hour to an hour and a half before meals, more often if case is severe (of course on an empty stomach). With this formula I have cured two cases, one scirrhus of right breast in 1907, the other one this summer, a cancerous sore at fourchette, with a small tumor in right abdominal region. The second case got well in a month; the ulcer at the fourchette scabbed over in a week.

Charles F. d'Artois Francis, M.D.
951 St. Marks Avenue, Brooklyn, N. Y.

3. The Rôle of Ptosis in Gynecology. R. M. Green.
4. Marine Hospital, Berck-Sur-Mer, Principally for Crippled Children. The Largest Institution of Its Type in the World. D. C. McMurtrie.

**2. Treatment of Pulmonary Tuberculosis by Means of the Class Method.**—N. K. Wood states that the results with this method show that 72½ per cent. of the patients are living at the end of six years. The class system of treatment furnishes a means by which patients can be kept under observation for periods of one to five years. It cultivates in the patients a spirit of great faithfulness toward the treatment after discharge from the class, which is evidenced by their continuance of outdoor sleeping and their marked after-improvement. A large proportion, 57 per cent., of the cases have returned to useful occupations for an average of 26½ months; and in some cases the tuberculous processes have been arrested without the patient losing a day's work.

**3. Rôle of Ptosis in Gynecology.**—R. M. Green points out that the rôle of ptosis in gynecology is primarily in the production of pelvic displacements, secondarily in association with and as a result of intrinsic disease of the pelvic viscera. In the one case it is a cause, in the other a symptom. When the ptosis is primary it may be congenital, in subjects of a depraved general physique, or acquired either by static errors or as a result of the fatigue and trauma incident to life. In any event, it should be considered as a possible cause of gynecological symptoms, especially backache, and the proper measures should be adopted for its cure or relief.

ance.—By A. T. Bristow. (See MEDICAL RECORD, December 21, 1912, page 1144.)

3. **Cancer of the Uterus.**—By H. J. Boldt. (See MEDICAL RECORD.)

4. **Aphasia.**—A. Gordon notes that not one special area alone is involved in the faculty of speech and in the various manifestations of the latter, but very probably several anatomical elements are concerned simultaneously, as the multiplicity of lesions ordinarily encountered in cases of aphasia is certainly striking. Marie's great merit consisted in calling attention to a chapter of pathological physiology which could no longer remain unchallenged. If Marie did not solve the question of localization of aphasia, he nevertheless demonstrated the necessity of looking for pathological data other than Broca's and Wernicke's areas.

7. **Blood Serum in the Treatment of Hemorrhage.**—G. H. A. Clowes and F. C. Busch emphasize the fact that blood serum is of considerable value in the treatment of all forms of hemorrhage due to low blood coagulability resulting from a diminished thrombin content. Human serum is in no wise superior to that of a variety of animals. Blood serum precipitated by means of a suitable mixture of acetone and ether is fully as effective as fresh serum, if not superior to it. Precipitated serum is freely soluble and possesses the advantage over fluid serum of being sterile, always available, and retaining indefinitely its capacity to stimulate coagulation of the blood. The product obtained from horse serum appears to yield more uniformly satisfactory results than that obtained from the sera of other animals, and exerts no deleterious effect. The determination of the rapidity with which sera and solutions of precipitated sera at comparable concentrations cause coagulation of citrated blood plasma affords a simple means of estimating the relative activity of the preparations in question, and consequently of standardizing precipitated sera for clinical purposes.

8. **Suspension Laryngoscopy.**—L. G. Kaempfer states that the two main points in favor of suspension laryngoscopy as a rational procedure are: first, the larynx is brought so near to the operator that manipulations are permitted that would be impossible with any other method of approach; second, the operator has both hands free with which to work instead of one as in all other methods. Another great advantage of suspension laryngoscopy is that secretions and blood tend to flow toward the pharyngeal roof which is the most dependent part. The opening of the larynx being in direct line of vision can easily be sponged free of blood and secretions. This enables the operator to make a longer and more thorough examination and to do more complete operations. He can, for instance, remove in one sitting small and not easily accessible growths or curette the larynx entirely free of tuberculous granulations.

1. **Pancreatic Lymphangitis and Chronic Pancreatitis.**—J. B. Deaver alludes to the frequency of pancreatic involvement in disease of the biliary tract. In ninety-nine cases of cholelithiasis operated on by him in 1911 there was some alteration of the pancreas in forty-five, and from this experience and that of others it would seem a natural inference that the pancreatic disease was secondary to the biliary disorder. There are certain objections, however, to this. Pancreatitis is more common in males and gallstone disease in females, though the anatomy and mechanism of the parts are identical in both. Again, the pancreas is often diseased without demonstrable disease in the biliary tract. This was the case in 36 per cent. of the cases of chronic pancreatitis and 25 per cent. of the acute cases in a series analyzed by the author. There are three other possible avenues of pancreatic infection: through the general circulation, by contiguity from adjoining tissues, and through the lymphatics. Infection through the systemic circulation is not often observed. It is rare in the systemic and pyemic processes and the conditions are not characteristic of bacteriemia. Infections by direct contiguity occur often in slowly perforating ulcers of the stomach and duodenum and the infection is then usually only local. It is to the lymphatics that one must look for the real source of pancreatic infection. Unlike certain other organs, the pancreas possesses no great hilum through which pass the blood-vessels and lymphatics. The lymphatics emerge through various points along its surface, and this accounts for the diffuse inflammation and irregular inflammatory swellings so often observed. This pancreatic lymphangitis (Arnsperger) is probably a forerunner of serious alterations in the parenchyma and stroma. When chronic pancreatitis has reached the stage of interlobular and intracinar fibrous deposits it is practically incurable, but in its incipiency, like lymphangitis elsewhere, it may be cured by the removal of the primary source of infection. The treatment is promising in the early stages, when it can be directed to the organs primarily involved. Pancreatitis is common and not rare; its presence should be suspected in all cases of obscure upper abdominal indigestion and, like other chronic inflammatory lesions of the abdomen, when it is uninfluenced in a reasonable length of time by medical measures it should receive surgical attention.

6. **Unilateral Renal Hematuria.**—A. Randall refers to the fact that in a majority of cases of unilateral renal hematuria nephritis with its concomitant congestion plays the leading rôle. In the second group the bleeding is from varicosities in the pelvis secondary to congestion resulting from certain of the extrinsic conditions. In a third group the hemorrhage is due to either rupture of a vessel or diapedesis of red blood-vessels, again secondary to congestion. While from the point of view of the patient who desires to be rid of this constant drain on the system, and from the point of view of the surgeon who is consulted, whatever the ultimate pathological condition is (and it may be one of a large category), the actual etiological factor causing the hematuria is a renal congestion, and this is most surely and successfully relieved by the performance of a nephrotomy.

8. **Hydronephrosis.**—H. Cabot defines hydronephrosis as a condition in which there exists a dilatation of the renal pelvis due to obstruction. It is this class of cases, not the advanced ones calling for nephrectomy, that he considers in his paper. The chief causes of obstruction are two: mobility of the kidney without corresponding

mobility of the ureter, and abnormalities of the renal vessels running to the lower pole of the kidney which are found in 2 to 4 per cent. of the cases. While some abnormality of the renal arteries has been shown to exist in about 25 per cent. of the cases, as has been pointed out by Kelly, these should be regarded as potential cases, becoming active only when the mobility of the kidney causes them to cut sharply across the pelvis. The symptoms in these early cases may suggest lithiasis, with or without abnormality of the urine, and, in rather rare cases, acute infection, but with persistently sterile urine. Diagnosis must be based first on convincing evidence of obstruction. Though this may be slight, the other possible causes of the symptoms must be excluded. Nothing of importance can be learned without the use of the cystoscope and ureteral catheter. The former alone is of little use, and ureteral catheterization will allow a positive diagnosis only after considerable dilatation has occurred. *X*-ray is of value only on the negative side. Pyelography is the mainstay of diagnosis. In this the important point is the question of the relation of the pelvis to its outlet. The ureter should leave the pelvis at its lowest point and not too abruptly. There should be proof that an obstruction of intermittent character exists to the outflow of urine from the pelvis, and that this obstruction is the cause of symptoms which are not caused by some other coexisting condition. Mere mobility of the kidney is wholly unimportant. In many of the cases, particularly those occurring on the left side and in strong muscular men, no mobility of the kidney can be demonstrated by ordinary methods. Convincing evidence can only be obtained by the radiogram taken after injection, the reproduction of the symptoms by the distention of the renal pelvis, and the exclusion of the other conditions which could cause the symptoms, chiefly, renal infections, renal calculus, and gallstones.

9. **The Ureterovesical Valve.**—J. W. Draper and W. F. Braash report the results and conclusions of a study of the function of the ureterovesical valve, with special reference to the question of the feasibility of ureteral meatotomy in human beings. The problem of safety of this operation resolves itself into the question whether there is special danger of hemorrhage or sepsis from accidental perforation of the bladder and whether its mechanical function will be so affected as to be dangerous to the patient. From the anatomy of the part they find these dangers minimized and practically negligible. The ill results of transplantation of the ureters into the bowel are attributed largely to the mechanical injury of the ureter and not to the destruction of the ureteral valve, the possibility of reflux being prevented much more by the ureter than by the obliquity of the valve itself. In experienced hands there is little or no danger in human beings from the operation of meatotomy through the operative cystoscope either as regards immediate hemorrhage or sepsis or as regards late results from injury to the kidney. The protection from reflux is affected at least as much by the physiological function of the ureter as by the check valve action at the meatus. These together, rather than the ureterovesical valve alone, constitute the "factor of safety" which prevents reflux. The ureter alone, almost without exception, sufficed experimentally to prevent reflux even if the ureterovesical valve had been destroyed. Section of the valve appeared to leave the protective ureteric function intact. The above data would confirm the opinion expressed by others that infections are seldom if ever ascending, but are rather hematogenous.

1. A Short Review of Obstetrics and Gynecology, 1887-1912. E. Malins.
2. The Complete Removal of Pleural Effusions by the Regulation of Intrathoracic Pressure During Aspiration (Oxygen Replacement). H. M. Davies.
3. A Case of Empyema in an Infant Aged Five Weeks, with Operation and Recovery. F. G. Chandler.
4. Is Anatomical Description Sufficiently Constructive? W. C. Morton.

1. **Progress in Obstetrics and Gynecology.**—E. Malins notes that perhaps in no other direction has the modern advance in obstetrics been more strongly marked than in the explanation of puerperal infections. In 1901 the total number of certified deaths in England from puerperal fever was 478; in 1910 the number fell to 161. For the prevention of puerperal infection the author has taught the following rules: Vaginal examinations are very seldom necessary; the size and shape of the pelvis and the position and movements of the child in the great majority of cases can be determined by external examination; all tears should be repaired at once, all douches avoided, and, lastly, rubber gloves, kept for this purpose only, should be constantly used. Blundell was not far from speaking the truth when he said that "he is the best accoucheur who keeps his hands in his pockets." The operation of cesarean section represents another great advance in obstetrics. In 1870 this operation was looked upon as the last desperate resource for the mother, with scarcely any hope of saving the child. Ten years later the maternal mortality was 85 per cent. During the period from 1906 to 1910 inclusive the maternal mortality was 8.1 per cent. A large opportunity has been offered for the radical treatment of fibroid tumors of the uterus. It has been clearly demonstrated that these growths are liable to changes of a degenerative kind which affect their growth, structure, and function. Consequently there is a greater risk in adopting a passive attitude toward them than formerly believed. The remarkably successful results of early operative treatment have been attended with a record that bids fair to emulate the history of ovariotomy.

2. **Complete Removal of Pleural Effusions with Oxygen Replacements.**—H. M. Davies states that although paracentesis of the chest is such a common procedure it does not seem to be at all fully realized that the ordinary method of withdrawing the fluid by aspiration is most unsatisfactory. Aspiration in itself is not devoid of danger, and it is frequently the cause of considerable discomfort to the patient. It may be said, moreover, that as a general rule never more than 50 per cent. of the fluid present can be withdrawn at a single tapping; and when, therefore, aspiration is used for the purpose of getting rid of an effusion, so as to allow of an examination of the lung by radioscopy and radiography, it is practically useless. Symptoms of distress—*e.g.* cough and pain—often appear when only 1 or 1½ liters of fluid have been withdrawn, yet the desire to take out as much fluid as possible does not infrequently tempt the operator to continue the aspiration after these symptoms have first appeared, thereby increasing the risks of edema or of cardiac embarrassment. When one side of the chest is full of fluid the removal of 1,500 c.c. is regarded as most satisfactory, but skiagrams will show that there is still an astonishing amount of fluid left behind. As the chest is a closed chamber it is obvious that if fluid is withdrawn, either a rapidly increasing negative pressure must be produced or the fluid must be replaced by some other substance. In paracentesis both mechanisms are brought into play, but there is a limit to the rapid alteration in the position of the mediastinum and to the expansion of the lungs when these are the seat of fibrotic changes or are surrounded by a thickened or adherent pleura, and when the traction exerted on these by the increasing negative pressure exceeds a certain grade the symptoms of distress so constantly seen during paracentesis are produced. The clear recognition of these facts suggests that if it were possible, during the process of

withdrawing fluid, to modify the intrathoracic changes produced by the increasing negative pressure, by introducing from without some non-irritating sterile substitute, the whole of the fluid could be withdrawn. The most obvious substitute is air, but it is found that of the three principal gases of the atmosphere, oxygen when in contact with the pleura is absorbed rapidly, while the nitrogen and carbon dioxide are absorbed at a much slower rate. Since, however, it is desirable that the pneumothorax produced should be absorbed as quickly as possible, the author has used oxygen instead of air for the replacement of the fluid in all cases. Under local anesthesia a needle connected with an aspirating apparatus is introduced into the fluid in the eighth intercostal space in the midaxillary line, and a needle connected with an oxygen apparatus is introduced in the fifth intercostal space in the same line. When the needles have been introduced it is absolutely essential that the manometer connected with the upper needle should show respiratory movements, and until these movements are obtained no oxygen must be allowed to escape through the needle. Fluid is now aspirated from the chest and the aspiration is continued until the patient either coughs or experiences the slightest pain. The aspiration is then immediately stopped, and 50 to 100 c.c. of oxygen are allowed to run in slowly. The pain or cough will at once disappear, and the aspiration is continued until the recurrence of some symptom demands the introduction of more oxygen. This process is continued until no more fluid can be withdrawn. Toward the end of the process oxygen will be found to escape with the fluid, and the proportion of oxygen introduced to fluid withdrawn must be increased.

2. Theories with Regard to Secondary Growths in Carcinoma of the Breast. M. Thorne.
3. Foreign Body in the Abdominal Cavity. L. B. Greene.

**1. Preoperative Diagnosis of Appendicitis.**—By W. Ewart. (See page 112.)

**2. Secondary Growths in Carcinoma of the Breast.**—M. Thorne presents an account of some of the theories that have been held from time to time with regard to the secondary growths of carcinoma of the breast. The embolic theory was the first to be advanced. According to this theory, cancer cells are carried by the blood stream from the primary growth to distant parts, where the cells are deposited, grow and multiply, and give rise to a tumor in all respects identical with that of the primary growth. This theory was a reasonable one. Sir James Paget suggested that cancer cells carried by the blood stream have a selective action with reference to the part to be attacked. Sir Watson Cheyne, in reviewing his cases, says that internal metastatic deposits are apparently more frequent now than formerly, due to the fact that patients escape local recurrence and live longer, and that thus the internal deposits have time to grow and attract attention. S. Handley, in his researches on cancer of the breast, quotes Goldmann's and Schmidt's work to show the degeneration which cancer cells undergo in the blood stream due to the inflammatory reaction set up by their presence, and thinks that the spread of cancer is due to the permeation of lymphatics by cancer cells. Handley, describing the spread of cancer in the parietes, says it occurs by the permeation of the lymphatic system like the spread of an invisible annular ringworm. The theory of infection, even of distal parts, by way of the lymphatics, commends itself strongly, but the question still is whether this is the only source of infection. G. L. Cheatle calls attention to the fact that there seems to be a certain relation between nerve supply and the growth of cancer, and that there seems a greater tendency for the disease to spread along the area of the particular nerve distribution in which it first occurred rather than independently into neighboring areas.

**On the Inheritance of Acquired Qualities.**—Meyer states the attitudes of Weismann and Semon on this subject. The former teachings as to parallel induction have recently received notable support from the experiments of Tower. Others had indeed shown that at certain stages of development heat and other forms of irritation had caused hereditary color changes in beetles and butterflies. Tower showed that experiments in the pupa stage alone resulted negatively; but if repeated at the periods of growth and maturity of the sexual cells the color alterations appeared in the progeny although not in the parents. Semon denied the claim that the action of the heat was confined to the germ cells alone, and asserted that the action upon the soma was latent. Semon has never gone very deeply into the inheritance of psychic characters, yet the human intellect appears to be the very best subject for study of the inheritance of acquired qualities. Semon admits that the subject is quite practicable. In this connection it may be mentioned that Przibram, having succeeded in taming some extremely wild grasshoppers which belong to the sphodromantes, their descendants in captivity showed an increasing disposition to tameness. The various excitabilities or "engrams" may also be modified by crossing or by "mendelizing" a strain of animals. The general tendency of all recent experiments is to show that the germ cells may be modified through the soma, much depending on the stage of development of the cells and the nature of the irritant. At the same time it is not desired that the germ cells may be directly stimulated by certain irritants, the soma being uninfluenced thereby.

**Therapy of Psychoneuroses.**—Vogt places under psychoneuroses neurasthenia, hysteria, hypochondria, psychasthenia, and certain cases of psychic degeneration and mild melancholia. All are characterized by absence of organic alterations and extreme subjective suffering. Failure of medical men to find lesions does not of course imply that somatic derangements do not exist. The treatment must be both bodily and mental. The psychic treatment must be regarded as causal, not symptomatic; we have to unravel the mental processes through which the mental states are produced and these processes do not much concern the intellect, for it is the affectivity which is disturbed in one or the other direction. This affectivity may be profoundly modified by a mere idea. The temper of the subject is naturally highly unstable and oscillating in character. A diagnosis must be made of the affect life and the emotional characteristics and the choice of treatment is regulated by the indications thereby furnished. The author repudiates the so-called intellectual method. All other methods, however unlike one another as they may appear, come under the head of suggestibility, whether produced by hypnotism or any mode whatever which overcomes the internal resistance. Here plain enlightenment, reasoning, and the like may cooperate in many cases, but not in the sense intended by advocates of the intellectual method. The greater the internal resistance the greater the probability that we shall have to overcome it eventually by hypnosis. The treatment is indeed educational but it is an education of the feelings.

**Paraldehyde Poisoning.**—Fornaco and Quarelli describe a case in detail. The drug was taken for insomnia, and patient had become addicted to its use so that the dosage was increased to almost incredible amounts. While taking it at the rate of over one pint a week a certain train of alarming symptoms developed for which he took a

single dose of nearly four ounces, and soon after was removed to the hospital half comatose and delirious. For the next eight days he lay in a condition exactly parallel with delirium tremens. A turn for the better occurred at the fifth day and by the tenth day he had become normal. As far as could be ascertained his recovery was permanent and he did not return to the habit. The picture of the intoxication was as follows: delirium, motor excitement (patient had one convulsion) escape of urine and feces, abundant diaphoresis, fever, thirst, etc. On the day of admission patient had to be restrained from jumping from the window. Of various measures tried the best appeared to be morphine hypodermics and pantopon internally.

## Münchener medizinische Wochenschrift.

*December* 24, 1912.

**Alimentary Angiorrhexis.**—Pick describes a form of acute acquired hemorrhagic diathesis of epidemic incidence. There were thirty-four patients, but one of whom was a female. All ages were involved and a number of occupations. There was some tendency to cumulation in certain houses. The author had opportunity of studying five cases in the clinic. The affection began for the most part *d'emblée* with pains in the legs which were followed by edema and extravasations of blood, especially marked about the knees. Naturally there was a suggestion of both peliosis rheumatica and Barlow's disease. Throughout, the affection was largely limited to the lower limbs. Involvement of the upper extremities was both inconstant and feeble. As the affection developed it became more and more localized about the knees, extending up the thighs and down the legs. The patients meanwhile took on an anemic and cachectic look much like that which accompanies true scurvy. The author cites Schönlein's original description of peliosis rheumatica in order to show that the two have little in common. There was no rheumatic element in his cases but a very pronounced scorbutus-like acquired hemorrhagic diathesis. To avoid the reproach of hastily postulating the existence of a new disease the author chooses to regard it as either a true scorbutus or Barlow's disease, since it partakes of the nature of both and also represents a transition form. An infectious element can be excluded, so that the etiology must be regarded as intimately bound up with the potash poor diet. The latter was notably poor in vegetables, and when it was corrected most of the patients showed marked improvement.

**Military Efficiency and Enteroptosis.**—Röder believes that enteroptotic subjects have a notable intolerance toward alcohol. The evidence comes to the front in the fact that when recruits admit or exhibit an alcohol intolerance they are found almost invariably to be enteroptotics; while *vice versa* the latter when questioned are found to be alcohol-intolerant. There should be certain criteria of enteroptosis. One of these is relatively low position of the navel. A normal relationship should exist between the stature and the distance between the superior sternal notch and navel. Another criterion consists of the fact that when a subject stands up he measures more about the waist than when lying down. Enteroptotics suffer from a variety of affections which impair their efficiency—cardiac anomalies, digestive disorders, headache, insomnia, moodiness. On a peace footing such subjects might well be rejected, on account of constant disabilities. The author is moved to ask whether or not enteroptosis solves, to a certain degree, the riddle of alcoholism. One person uses alcohol throughout life with relative immunity, while another quickly succumbs to its malign influence. In other words does enteroptosis as an expression of degeneracy, enable alcoholism to play the rôle of a decimating disease?

**For and Against Pituitrin.**—Rieck makes a short contribution to this subject. The good effects of the new remedy have received due heed so that whatever may be said of adverse significance will be timely. This, however, affects the status of the drug only in the individual case, for generalizations are not to be expected. The author relates a case of retained placenta following abortion, in the fourth month. In this case both ergotin and pituitrin failed to dilate the os, so that it was necessary to dilate artificially and use the curette. Now in this instance pituitrin was far from being inert, for it apparently contracted the cervix and thereby interfered with the normal course of delivery. This untoward result, however, is contrasted with one in which exhibition of pituitrin in a case of placenta previa did away with the usual procedure of rupture of membranes, metreurysis and tamponade with attendant risk of infection.

## Deutsche medizinische Wochenschrift.

*December* 26, 1912.

**General Infection with the Bacillus Pyocyaneus.**—Klieneberger relates the following case: male, aged 47, with long history of urinary lithiasis, and one operation of nephrotomy for stone. *X*-rays show that he still has renal calculi on both sides. Urine infected. Also has pulmonary symptoms—cough and purulent sputum. Upon admission to the hospital was found to have evidences of bronchopneumonia, with tubercle bacilli absent. Pneumococci were cultivated from the sputum. Under mild measures his chest findings improved greatly and he was out of bed, when he was suddenly stricken with a chill and other evidences of a toxemia. Fever over 40 deg. C. Blood smears were at once made and the *Bacillus pyocyaneus* was found to be present. After a series of chills at irregular intervals the symptoms ceased abruptly and he was left in good physical shape. The Widal reaction had been negative. Pneumococci still persisted in the sputum. The urine, which had originally contained staphylococci only was now rich in the *Bacillus pyocyaneus*. The latter germ was virulent to guinea pigs.

**Treatment of Mnemasthenia.**—Rauschberg concludes a serial article on this subject in part as follows. He refers naturally to idiopathic or neuropathic memory failure. There has never been a somatic treatment recommended for this condition. In acute severe cases patients should enter sanatoria, there to receive dietetic and physical treatment, the latter comprising head massage, galvanization, sinusoidal voltaization, the franklinic douche and hydrotherapy. Of internal remedies the author can only vouch for substances which contain phosphorus—glycerophosphates, hypophosphites, lecithin, and spermin. When there are evidences of general cerebrasthenia life in the country with farming and gardening or a moderate amount of sport in the open air are to be recommended. In mild but obstinate cases, mountain sojourn or seashore life, or a sea voyage may be tested.

**The Specific Treatment of Tuberculosis.**—Levy refers incidentally to the Friedmann method of immunizing with nonvirulent living cultures. The use of dead cultures is already held by many to be insufficient for cure, despite its advocacy by Koch. Both living and dead cultures possess advantages and disadvantages. It has been sought to make use of dying cultures which in a measure combine the qualities of the living and the dead bacilli. The slow death of the cultures is effected artificially by chemically indifferent substances. The author holds that the specific treatment of the future must consist of active immunization, but that the latter should be regarded as only relative and temporary. After from six to twelve months the resistance which has developed should begin to decline, and should be developed anew, as in the case of revaccination for smallpox. The idea must be paramount that we are to set up an artificial vaccination-tuberculosis which will protect the patient for a time from the natural disease.

# Insurance Medicine.

## SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

### THE APPLICATION FOR INSURANCE.

The application blank is usually divided into three parts, namely, the application for insurance to be signed by the applicant and witnessed by the agent, the statements to the medical examiner to be signed by the applicant and witnessed by the examiner, and the medical report of the physical examination by the examiner. As the applicant only takes a passive part in the report of the physical examination, no further reference to it will appear in the discussion of this subject. The statements in the application and the statements to the medical examiner, however, constitute a declaration which forms the basis of a proposed contract for insurance. As the transaction is conducted for the purpose of making this an actual binding contract, the blanks are made as brief and definite as possible, but comprehensive enough to preclude any justification for the omission or distortion of relevant information. In order that the legality of the proceeding may be strictly observed it is imperative to have every question in the blank fully, clearly, and truthfully answered, to avoid striking out printed words, and making erasures, and to refrain from the employment of dashes, lines, ditto marks or any other mark in the place of written answers. If any change is demanded in the written answers, a line must be drawn through the part to be altered and the change must be attested by the initials of the applicant with the date of the attestation affixed. Even with these precautions faithfully followed, a company will have a hard struggle to secure a favorable judgment in a suit instigated in the case of fraud.

Under the older laws applicants for life insurance were required to warrant the truth of all statements made by them in the application and to the medical examiners. Any misstatement of fact, whether material or not, was held under the law of warranty to give the company legal grounds upon which to avoid payment. These were harsh provisions and were created through a feeling of defenselessness against fraud at a time when the companies were in their youth, with meager facilities for investigation and inspection of risks. No reliable company, however, took advantage of this right unless intolerable fraud was practiced. On the contrary, life insurance companies have been criticised, not for seeking to avoid the payment of just claims, but for too frequently paying claims which should have been resisted. Under the latest insurance laws, in a number of the states, all statements made by the applicant in the absence of fraud, are deemed to be representations and not warranties. The distinction between these terms is that a warranted statement must be true regardless of materiality, while a representation need only be true substantially in all matters material to the risk. According to these recent laws no statement can avert or be used in defense of a claim unless it is contained in the written application. If any material statements therein are found to be untrue the contract according to its terms may become null and void.

It would seem, with well-defined laws, that the companies are amply protected. The truth is, however, that a company usually feels itself open to congratulations if it succeeds in getting a favorable verdict in a case even where there is glaring misrepresentation. Public sentiment, as reflected in the average jury, is too apt to regard the companies as immensely rich corporations and to ignore the fact that life insurance is effected by the money belonging entirely to the policyholders of the company and that the officers are merely managers, this being especially true in the case of the mutual and mixed companies and these companies write the great bulk of the life insurance. In consequence of this feeling the companies are compelled at times to pay unjust claims and the expense of litigation, every dollar of which must come out of the money belonging to innocent and honest policyholders. These losses will be largely prevented by straightforward, truthful and unreserved answers to the questions on the application blank.

In view of the preceding remarks it will be apparent that both the applicant and examiner should fully understand every phrase and term appearing in the application blank. In general experience it is found that a very small percentage of applicants take the trouble to inform themselves of the stipulations which are printed plainly on the blanks or to even read the photographed copy of the application which is usually attached to the policy. This is found to be true even with important business men and lawyers who scrutinize the terms of their usual business transactions with infinite care and yet who affix their signatures to applications for insurance with scarcely a glance at the contents.

*The Application.*—The duty of directing the attention of the applicant to the stipulations in the application, as well as having the questions properly answered, belongs to the agent, but the latter will rarely volunteer to elucidate restrictions or obligations of any sort which might cause hesitation or doubt in the mind of the former. The examiner will often be regarded in the light of an adviser by the applicant at the time of the examination, and a knowledge of the terms and their meaning will be found useful. The most important points to remember are as follows:

1—The usual stipulation that all the statements and answers in the application, and all those made to the company's medical examiner in continuation of the application are true and are offered to the company as an inducement to issue the proposed policy, which shall not take effect unless and until after the first premium shall have been paid during the continuation in good health of the applicant, and unless also the policy shall have been issued during the applicant's continuance in good health. The only exception to this condition is the issuance of a binding receipt which puts the insurance in force on the date of the said receipt, provided the application is subsequently approved and the policy issued.

2—The restrictions in regard to hazardous occupations or employments which are clearly set forth in the blanks.

3—The suicide clause, whereby it is understood and agreed that the risk will not be covered by the policy if death by suicide takes place within a stated period of time, whether the policyholder is sane or insane. It may be added here that it has been satisfactorily demonstrated from experience that sane persons will commit suicide when there is no suicide clause, so that their beneficiaries may collect the insurance. In other words, there is a consider-

ably greater mortality from deaths by suicide in the first few policy years when there is no restriction clause in the application.

4—War clause. Restrictions in reference to military and naval service during war have been removed from the applications and policies of many companies. This liberality was actuated by the experience of the companies during the civil and contemporaneous European wars, in which no disastrous results were encountered. Since then, however, a much larger proportion of the population has become accustomed to carry life insurance, and it is questioned in the minds of some whether the complete removal of the war clause would prove to be a wise procedure in the event of a prolonged and extensive war.

*The Statements to the Medical Examiner.*—The duty of seeing that all the statements of the applicant to the medical examiner are duly set forth in a form which will meet the legal requirements devolves upon the medical examiner. These requirements have been described and emphasized in the preceding lines. A carelessly framed report has fairly often proved costly to the companies. Misunderstandings and loopholes for the dodging of obligations will be largely prevented when the examiner insists on a frank, clearly defined, unreserved answer to every question and the avoidance of vague and ambiguous terms. Every question should be answered even when the information has already been given in another part of the application, as a repetition will do no harm, whereas some unanswered question often gives the desired chance to the acute lawyer to make a point against the company.

---

**Simple and Exact Uranalysis.**—Lichtenstein calls attention to the great importance of thorough examination of the urine of applicants for life insurance. Uranalysis gives us knowledge of the condition of the genitourinary passages, of metabolism, of the work of the heart and blood vessels. The following things must be had by every insurance examiner: a good microscope, a centrifuge (hand, water, or electric), good fresh chemical reagents. The urine should be passed into two vessels, a small portion into the first and the rest into the second glass. The first glass shows the condition of the urethra; if urethritis is present, this glass contains pus and the urine may give reactions for albumin, even when filtered. The second glass is the important one to exclude such local conditions. The specific gravity should always be taken; it normally ranges between 1015 and 1020. Color should be noted. It should be yellowish, the urine being clear and transparent. Dark urine, which may contain bile pigments, gives yellow foam on shaking. To be sure of their existence pure nitric acid with admixture of fuming nitric acid should be used, the urine being layered over the reagent. A ring showing a play of colors—green, blue, violet, red, reddish yellow—forms at the junction of the two.

Litmus paper should be used to test reaction. Normal urine reacts faintly acid. After much vegetable food alkaline reaction may be noted. Occasionally, it is amphoteric. Constant alkalinity shows that fermentation is going on, which usually accompanies disease of bladder, ureter, or pelvis of the kidney. The following tables give a review of the tests that should follow:

| Urine cloudy. Upper portion of urine in test tube boiled. | | | |
|---|---|---|---|
| Cloudiness disappears | Cloudiness increases in the boiled portion | | Cloudiness does not change |
| | and remains on addition of acetic acid | and disappears on addition of acetic acid | |
| Signifies the presence of urates | Signifies pyuria | Signifies phosphaturia or "carbonaturia" | Signifies presence of mucin, bacteria or semen. Microscopic examination decides between these |
| | If cloudiness decreases but does not disappear pyuria and phosphaturia are present | | |

| Urine Clear. Upper Portion of Urine in Test Tube Boiled | | |
|---|---|---|
| The boiled urine becomes cloudy | The boiled portion remains clear | |
| and the cloudiness remains on addition of acetic acid | and the cloudiness disappears on addition of acetic acid | But becomes cloudy on addition of acetic acid |
| Signifies albuminuria | Signifies phosphaturia | Signifies albuminuria |

The urine should always be filtered before the following tests are carried out.

1. Albumin (a) Boiling test: A few centimeters of urine are placed in a test tube and its upper portion heated to boiling. Then acetic acid is added drop by drop. Increasing cloudiness means presence of albumin. (b) Layer test: Urine is layered over a few centimeters of pure nitric acid in an obliquely held test tube. In the presence of albumin a sharply defined milky "albumin ring" is formed at the junction of the two fluids. If the test is doubtful (c) McWilliam's solution (20 per cent. sulphosalicylic acid) is used. This solution is added drop by drop to a few centimeters of unboiled urine, and very definite cloudiness appears in the presence of albumin.

2. Sugar. Two methods are sufficient, but both should be used. (a) Nylander's reagent (½ to 1 cm.) is added to four or five centimeters of urine and the mixture is boiled. Black precipitate appears in the presence of sugar. (b) Three volumes of Haines' solution are added to one volume of urine and the mixture boiled. A yellowish red precipitate means the presence of sugar. Haines' reagent: Copper sulphate 2.0, distilled water 15.0, glycerin 15.0, 5 per cent. solution of potassium hydrate 150.0. This solution keeps for a long time.

The sediment must then be examined, leucocytes, epithelial cells, crystals, formed kidney elements, casts, etc., being carefully searched for. Examination with high, dry power should follow inspection of the sediment with a low power lens.—*Blätter für Vertrauensärzte der Lebensversicherung*, Vol. III, No. 4.

**Life Insurance of the Future.**—George W. Hopkins predicts a glowing future for life insurance. It will not be government insurance so long as the purchase of insurance is optional with the citizen, as it probably always will be. According to the author, the companies of the future will be mutual companies. "Investment insurance" will be abolished by compelling the companies to separate their savings, or investment business, from their insurance business.—*Medical Review of Reviews.*

# Book Reviews.

THE CARE OF THE SKIN AND HAIR. By WILLIAM ALLEN PUSEY, A.M., M.D. Professor of Dermatology in the University of Illinois. New York and London: D. Appleton and Company, 1912.

THE branch of medicine, commonly called cosmetic treatment, has so long been under the ban that it is a boon to those interested to find a book of this kind written by so eminent an authority as Dr. Pusey. The general purpose of the book is well expressed by the author in his preface in which he says that the skin and its commoner disorders are here considered from the standpoint of the intelligent person both because of the practical personal importance of these subjects "and as a part of one's general knowledge." The writer's aim, so well realized has been to present "a book chiefly on the hygiene of the skin, not a book on the self-treatment of skin diseases, and certainly not one to fasten the mischievous habit of self-medication." The text is "sane and interesting" and should be in the hands not only of the dermatologist but of the general practitioner. It is equally suitable for the layman who is anxious to know how to care for the skin. Among the subjects considered are the structure, nutrition, and functions of the skin; the care of the general health in relation to the skin; hygiene of the skin; diet, bathing, soaps, powders, creams; the care of the face; inflammation of the skin; disorders of the face such as acne and blackheads; certain defects in the skin; the structure and care of the hair, and certain of its disorders. The value of the book is enhanced by a good index.

THE CARE OF THE SKIN IN HEALTH. By W. ALLAN JAMIESON, M.D., F.R.C.P.E. Knight of Grace of St. John of Jerusalem. Surgeon The King's Body-guard for Scotland, The Royal Company of Archers. Consulting Physician for Diseases of the Skin, Edinburgh Royal Infirmary. London: Oxford University Press, 1912.

THE writer from his long experience in the study of diseases of the skin has been impressed with the fact that considerable ignorance obtains regarding the proper care of the skin in health. In this handbook he considers first the structure of the skin. This section is followed by one devoted to the care of the skin. The subject of bathing is treated in a most interesting manner. The writer sets forth the two purposes of the bath—cleansing and tonic action. The varying effects of the cold bath are pointed out. Friction alone can cleanse the skin and no soap except for the hands is advised for the morning ablution. Hot and warm baths are then considered. Final chapters deal with the care of the hair and nails, clothing, and diet. This little volume of 109 pages abounds in helpful suggestions and can scarcely fail to accomplish the purpose for which it was written.

MAKING GOOD ON PRIVATE DUTY. Practical Hints to Graduate Nurses. By HARRIET CAMP LOUNSBURY, R.N., President West Virginia State Nurses' Association; Sanitary School Inspector for Charleston Independent School District. "Not to be ministered unto, but to minister." Price, $1.00 net. Philadelphia & London: J. B. Lippincott Company.

IN spite of the continuous improvement in methods and change in technique, nevertheless the writer of this helpful volume realizes the need of counsel, help, and guidance felt by the young beginner in the nursing world. In these pages are presented many hints that are the fruit of experience not only of the author but of many other graduate nurses as well. Little or nothing commonly taught in the classroom is treated in the chapter on obstetrical nursing. Suggestions about the layette, the baby's bath, and a table for calculating the date of confinement are given. Not the least helpful suggestion is that concerning the tactful treatment of the family cook. Some of the topics considered in the thirteen chapters are the nurse and her patient, the nurse and the doctor, the nurse herself, the nurse and her patient's family, friends, and servants; general remarks on foods and feeding; why do nurses complain; the nurse as a teacher; convalescence; how shall a nurse occupy her days of waiting; bathing the baby; the valley of the shadow. The book is sure to prove useful, practical, and inspiring to nurses.

THE KALLIKAK FAMILY. A Study in Feeble-Mindedness. By HENRY HERBERT GODDARD, Ph.D., Director of the Research Laboratory of the Training School at Vineland, New Jersey, for Feeble-Minded Girls and Boys. Price, $1.50 net. New York: The Macmillan Company, 1912.

THE Vineland research laboratory has made a study of the families of more than 300 feeble-minded children by means of field workers. The results of this study show that 65 per cent. of these children have the hereditary taint. The "Kallikak" family was one of the families studied, and the book is a story of real people. It reveals a condition of things truly astounding, and illustrates the working of the Mendelian law as applied to human beings. The Kallikak family, says the author of the book, presents a natural experiment in heredity. A young man of good family becomes through two women the ancestor of two lines of descendants—the one characterized by thoroughly good, respectable, normal citizenship, with almost no exceptions; the other equally characterized by mental defect in every generation. On the good side were traced 496 people more or less prominent in all walks of life, without a single example of mental defect. On the bad side, 480 direct descendants were traced; and from marriage with other families 1,146 were recorded. Of the 480 descendants on the bad side 143 were feeble-minded, 36 illegitimate, 33 prostitutes, 24 drunkards, 3 epileptics, 3 criminals, 8 kept houses of prostitution, and 46 were reputed to be normal. Of the larger group (1,146) on the bad side, 262 were feeble-minded, 197 normal, the remainder undetermined. This carefully worked out analysis and painstaking study of a concrete example of the workings of the laws of heredity as related to feeble-mindedness, is highly praiseworthy, and raises the question of "What is to be done?" The author replies: "We cannot successfully cope with these conditions until we recognize feeble-mindedness and its hereditary nature, recognize it early, and take care of it." We recommend the story of the Kallikak Family to the careful consideration of both the medical and the lay reader. It is a story as interesting as a romance, written in a pleasing style. At the same time it is a real biography of people who have lived. It conveys a moral and a great lesson.

PATHFINDERS IN MEDICINE. By VICTOR ROBINSON. With a letter from Ernst Haeckel and an Introduction by Abraham Jacobi. Price, $2.50. New York: Medical Review of Reviews, 1912.

MR. VICTOR ROBINSON in this work has entered an almost untrodden field of literature. The poets of the great dead and gone physicians have been few and far between. The term poet is used advisedly with regard to Mr. Robinson's latest writing, for although it is not in verse the work in question is not the less poetry. Perhaps the most distinctive feature of the book is the language employed; the author has a fine choice of words and a happy knack of phrasing while at times he is shrewdly epigrammatic; indeed, he is amply endowed with what is usually termed the literary instinct. The roll of great physicians is a long one, so great and so long, in truth, that it must severely tax the discriminating faculties of an author to choose those most worthy of having the tale of their lives and deeds handed down to posterity. There are always in every calling some three or four who stand head and shoulders above their fellows, but after these giants there is a good deal of difficulty in selecting discreetly. While the author's selection of "pathfinders" on the whole is good, there are yet notable omissions, and one or two of those included can hardly be described as great pathfinders in medicine. For example, Pasteur assuredly merits a place in a list of the greatest pioneers of medicine, and to a lesser extent Harvey and Lister, and although Darwin was pre-eminent in science it was not in medical science that he shone so brightly. However, in spite of these and certain other blemishes in the work, Mr. Robinson has done the medical profession a good service by depicting this gallery of its noted members, and it is to be hoped that in the near future the author will add to the gallery and earn the further gratitude of medical readers.

DER PRIMÄRE LUNGENHERD BEI DER TUBERKULOSE DER KINDER. Von Dr. ANTON GHON. a. ö. Professor der pathologischen Anatomie an der deutschen Universität in Prag. Mit 72 Textabbildungen, 1 schwarzen und 1 farbigen Tafel. Price 8.50 marks ($2.15). Berlin und Wien: Urban & Schwarzenberg; New York: Rebman Company, 1912.

IN this monograph of 144 pages there is presented a review of the author's pathological experience in confirmation of Parrot's law, namely, that in children there occurs no pulmonary tuberculous affection without an accompanying affection of the neighboring bronchial lymph nodes; and vice versa, there is no tuberculous affection of the bronchial lymph nodes without an accompanying lesion in the lungs. The author's material consisted of 747 cases, certainly an ample number, from which valid inductions may be drawn. His conclusions confirm those previously announced by Küss and Albrecht.

# Society Reports.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, Held December 5, 1912.*

THE PRESIDENT, DR. WILLIAM M. POLK, IN THE CHAIR.

**Resolutions on a Commission to Report on the Waters of the Hot Springs of Arkansas.**—Dr. SIMON BARUCH presented this resolution, which was seconded and unanimously carried: *Whereas:* A bill has been introduced in Congress to authorize the appointment of a Commission to determine the physiological and therapeutic action of the hot water of the springs on the U. S. Reservation at Hot Springs, Arkansas, and *Whereas:* The waters of these springs have hitherto been used empirically with more or less success and it is important that their real therapeutic properties be ascertained with absolute impartiality, it is hereby *Resolved:* That the New York Academy of Medicine desires to express its approval of the Commission proposed and of any appropriation necessary for the conduct of its investigations. *Resolved:* That it is the sense of this Academy that the unbiased report of a Commission appointed under the auspices of the Surgeon-General of the United States Army may stimulate similar investigations of the numerous mineral springs in our country and diminish the annual exodus of health and recreation seekers to foreign lands by access to reliable information on the health-giving properties of the springs of the United States of America. *Resolved:* That a copy of these resolutions be transmitted to the Surgeon-General of the Army and to Medical Director Harry W. Hallock, in charge of the Hot Springs Reservation.

**A Discussion of Bone Transplantation (without Periosteum), with Lantern Slides of Cases and Experiments Showing the Necessity of Preserving the Periosteum.**—Dr. CLARENCE A. MCWILLIAMS presented this communication. He said that for a proper understanding of the subject it seemed advisable to review the conclusions reached by Axhausen, Macewen, and Murphy. To put it briefly Axhausen, in his classical work on this subject, claimed that the best results were obtained when living, autogenous, periosteum-covered transplants were used. Macewen held that the bone cells of the fully developed bone could produce new osteoblasts and so form new bone whether covered with periosteum or not. Murphy, in an article on "Bone Transplantation" in the *Journal of the American Medical Association*, April 6, 1912, concluded that the following laws should be followed if the best results were to be obtained from bone transplantation: (1) The periosteum fully detached from the bone and transplanted into a fatty or muscular tissue bed in the same individual, if he were young, might produce a lasting bone deposit; transplanted into another individual or animal of the same species and under the same conditions, rarely, if ever, produced a permanent bone deposit; transplanted into another species it never produced a permanent bone deposit. (2) Periosteal strips elevated at one end from the bone and attached at the other, if turned out into muscle or fat, reproduced regularly bone on their under surfaces for the greater portion of their entire length. (3) Transplanted into other individuals or animals of the same species and contacting at one end with exposed or freshened bone a graft rarely produced permanent bone even for a small extent of its basal attachment, and never produced bone for its full length. (4) Bone transplanted with its periosteum into muscle fat, etc., in the same individual, and free from bony contact practically always died and was absorbed, except in the case of very young children or infants. (5) Bone transplanted without its periosteum into muscular or fatty cellular tissue always died and was absorbed. (6) Bone with or without periosteum transplanted in the same individual and contacted with other living osteogenetic bone at one or both ends of the transplant always became united to the living fragment and acted as a scaffolding for the reproduction of new bone of the same size and shape as the transplanted fragment if asepsis was attained. (7) The transplanted fragment, no matter how large or how small, was always ultimately absorbed. The rôle it played was to give mechanical support to the capillaries and blood vessels with their living osteogenetic cells, as they advanced from the living bone at both ends of the transplanted fragment. Bony union and much support was given by the new growth long before the transplant was absorbed. Bone covered at the ends by cartilage and on the sides by periosteum, even when contacted with living bone denuded of its periosteum, died and was wholly absorbed. Dr. McWilliams thought that Dr. Murphy did not make it exactly clear in regard to the function of the periosteum in these grafts. From his investigations Macewen seemed to think that the periosteum was unnecessary. But in three cases out of four in which he himself had grafted bone without periosteum, the grafts had been absorbed and this taught him that the periosteum was important and should be included in the graft. If the periosteum was removed entirely no new bone formed to any extent, and the deformity in the bone persisted; if the periosteum was preserved the cavity filled up and the defect was corrected. Some periosteum should always be left in the site of the lesions to be corrected. While the graft must be in contact with living bone its subsequent life depended largely on its getting sufficient nourishment. One could never be quite sure that some of the cells in the graft did not die, and if there was periosteum these cells could be replaced from the inner osteogenetic layer. The question in his mind was whether success was not dependent on the blood supply. He had had the opportunity to experiment with animals in the surgical experimental laboratory of Cornell University and his observations had shown that a defect in bone could be corrected by a graft irrespective of periosteum. He had not done this on the human being and there was a question whether the same thing held true for human beings as for animals. If the filling of a gap in bone by a bony graft was dependent on the blood supply, then the smaller the graft the better would be the success. The three points to be especially emphasized in making a bone graft were avoidance of the Esmarck's bandage, avoidance of drainage, and the preservation of a rigid asepsis. Dr. McWilliams then described four cases in which he had made bone transplantations. In one of the first of these he had made a subperiosteal resection of four inches of a rib which he used to repair a defect in the half of a lower jaw in the same individual; the rib was sutured in place with chromatized gut and seemed as though it would live for a time, but disappeared entirely by the end of five months. The gap in the rib was filled in by a mass of fibrous tissue. This seemed to be in direct contradiction to Murphy's second conclusion. If the rib had been split longitudinally and half covered with periosteum the result would have been better. In the second case, in operating on an inguinal hernia, he had strengthened the hernia with a piece of rib. The *x*-ray, four months after the operation, showed that the rib had been entirely absorbed and that fibrous tissue was left which would materially strengthen the hernial repair. The third case was instructive, as it showed what should not be done. The patient was a man who had sustained a fracture of the humerus which refused to unite and in the course of a month two sequestra had separated. The fragments were freshened and a Lane's plate applied. Two months later the plate had to be removed because of a fistula. He then freshened the ends of the bone, inserted a portion of rib, and applied the Lane's plate, because the section of rib did not fit closely. Perfect primary union had followed and there was no sinus. The *x*-ray showed a growth of new bone from the fragments and the periosteum and the rib were not absorbed. He attributed this result to the fact that the rib was in an osteogenetic bed. A bone graft was better than a Lane's plate, since union of fragments did not take place at times because of lack of osteogenetic power, and a Lane's plate retarded rather than helped osteogenesis. The fourth case was that of a birth fracture of the tibia and fibula which had not united at the end of seventeen months, when Dr. McWilliams transplanted a piece from the other tibia. The graft was tightly wedged between the fragments in the medullary cavity, the lower part of the fragment being sutured with chromic gut. There was primary union. *X*-rays taken at times during the following six months showed the graft gradually disappearing. This was due to lack of periosteum or a deficient blood supply. He then did another operation, transplanting a piece of tibia covered with periosteum on three sides. This case seemed to contradict the first statement made by Dr. Murphy in his conclusions. Dr. McWilliams exhibited lantern slides showing the various stages in an operation by which a finger was transplanted to replace the nose in a man who had suffered an accident tearing off the nose from the frontal bone down. Following the plan of Finney and McGraw, he had placed the man in a plaste-of-Paris jacket with the hand in position for the operation the night previous. Not only was the entire bony structure of the nose gone but the soft parts as well, with the exception of a portion of the left nostril. At the operation the finger nail was removed and the phalanx scraped; this was sutured to the frontal bone.

The skin and flesh of the finger and the wound in the face were united. When circulation of the blood had been established, the finger was amputated under novocaine anesthesia and the first phalanx sutured to the face. The top of the last phalanx seemed to be solidly united to the frontal bone. The result was a very creditable nose, showing some irregularity at the lower portion which the speaker said he intended to correct later. The tendons had not been disturbed and were still in place. The experiments on dogs seemed at first sight to contradict the facts brought out in bone transplantation in human beings. He had transplanted sections of the rib into the muscular tissue of the abdomen of the same dog and the *x*-ray showed that the bone lived and grew if there was sufficient blood supply. A small graft stood a better chance of getting a sufficient blood supply than a larger one and was therefore more likely to continue to live. Of course it was possible that some osteoblasts might have been taken with the graft, but there was no way of finding this out. In one instance the periosteum of a corpse after being in cold storage for one hundred and sixty-eight hours produced new bone after transplantation, and after eight months there was not the slightest sign of absorption. Large grafts if broken into pieces would live in the soft parts if the blood supply was sufficient. A section of rib without periosteum could be grafted on another rib in a dog and would live, but a graft on a graft without periosteum would not live. The pathologist's report in regard to these grafts in dogs showed the presence of many osteoblasts and that new bone was being formed. This seemed to show that in dogs bone was formed from bone independent from periosteum, endosteum, or marrow. The new bone seemed to come from the cortex itself. This was due to the blood supply. If this happened in the dog, why not in the human being? He thought because the blood supply was insufficient and not because the bone was without periosteum. Perhaps the point might be made that if the periosteum was present the blood supply was apt to be more active. In summing up his observations, Dr. McWilliams said that in order that a bone graft might be successful it should be living and from the same individual; it should have wide contact with its new bed; if it was a small graft the periosteum might be disregarded; if it was larger the periosteum must be left; the periosteum survived because of the blood supply; the graft should be transplanted quickly in order that as few cells as possible should die; grafts from different species did not live because of serological differences, and usually grafts from different individuals of the same species suffered the same fate.

Dr. George E. Brewer said that this question of the repair of lost tissues in the bones of the extremities was a most important one, one of the most important that was being considered by the surgeons to-day. They all remembered the famous experiments of Dr. Phelps made twenty-five years ago in which he attempted to repair the tissues in the arm of a patient by engrafting part of the tibia of a dog. The proximal extremity was connected with the distal; this was carried on for weeks and the result was a failure. Dr. Murray had attached the skin of a pig to an individual who had lost much tissue because of a burn and this was also a failure. Both of these failures demonstrated what was now generally understood, that grafts from another species could not be successful. In the repair of these bone injuries certain questions were brought up: (1) Did we secure much from the little bone graft that had been transplanted? (2) Was the foreign body tolerated? (3) Was there a certain amount of new bone formation? The experimental work done showed that all three processes might take place. In the first place the question arose, could they obtain a living graft of bone? It was easy to assume that the graft was living if functionally it gave good results, but they should have autopsies, *x*-ray pictures, and demonstrations to prove this. Tuffier of Paris had transplanted the fibula to where the femur had been removed because of the existence of gangrene; the leg of this patient had been removed because of gangrene and the fibula was transplanted into the cleft left. Amputation was found to be required afterwards when it was seen that the union was fairly good and that the transplantated bone had not been entirely absorbed. In this instance they had a living graft. At the meeting of the Clinical Surgical Society of Paris many interesting reports were made. In one instance there was transplanted a portion of the fibula from a limb that had been amputated for sarcoma. The periosteal cuff of the bone he believed to be essential for its preservation. After a number of months the *x*-ray gave evidences of necrosis, but at the end of eighteen months the results of the operation were perfect. Another reported case was that in which there was an autogenous graft and there was not the slightest change to indicate necrosis, absorption, or rarification. At the end of one year the results were perfect. Dr. Brewer thought they could say after these experiences, as well as after a number of other experiences that had been reported, that they had every reason to believe that the autogenous graft, placed between the two fragment of bone where there was tissue that had been lost, could complete the graft without any following absorption of the tissues, without any deposition of new bone. Another case was recalled in which a patient lost the radius as the result of osteomyelitis. A portion of the ulna from the same arm was turned over on a hinge and fitted into the gap. When they could get a good blood supply in these cases the results were surprising. To obtain good and complete results it should be remembered that the periosteum should be kept intact and the bones should be approximated, periosteum to periosteum, cortex to cortex, and medulla to medulla, and then the bone graft would live and the parts unite. With regard to grafting bone from one individual to another, Dr. Brewer referred to a certain German surgeon who had done this and examined his case at autopsy; the result of this examination showed that not much was to be expected in these cases. The patient referred to had a sarcoma of the upper portion of the tibia and one-third of it had been removed. It seemed to the surgeon that this was a case requiring amputation. He made, however, a careful implantation with the wound healing primarily. The results in this case were apparently satisfactory. No irritation followed this procedure. At the end of nine months there was a recurrence of the sarcoma and the limb was removed. Multiple sections showed that the bone was covered with a complete periosteum and that the growth which was or had been introduced was absolutely dead. However, this graft remained in place without serious disturbances for nine months. One year ago he reported the case of a patient with a sarcoma at the lower end of the radius. From the *x*-ray it was shown that there only remained a shell. The tumor was removed and was found to be a mixed celled sarcoma and not a myeloma. The wound was closed. Within forty-eight hours a man was brought to the hospital because of a gun-shot wound and died. A portion of his radius, the same size and shape, was removed and transplanted. The patient was kept in splints for several weeks and left the hospital two months later in good condition. The *x*-ray at the end of one month showed no change in the bone; at the end of two months there was a slight rarefaction; at the end of three months a greater rarefaction. He was then lost sight of for six months. Nine months or more after the operation there was found to be a considerable amount of rarefaction, but there was a considerable amount of bony union, especially of the proximal extremity and surrounding the upper portion of the extremity. To-day the man was dispensing papers in his ordinary way. There was but slight evidence of motion at the junction of the fragments. The motion at the wrist was by no means perfect. Dr. Brewer believed in leaving the graft in place; foreign bodies in the arm would be tolerated by the tissues. Within one, two, or three years there might occur complete absorption and then a regeneration of bone might take place. One should not expect bone transplanted from one individual to another to become a living bone but only a foreign substance that was tolerated. He believed that it was, in obtaining successes in these cases, more a question of blood supply. It was also wrong to argue that what was obtained from animal experimentation should apply to the human being; they might have a living bone in animals but, under the same conditions, this would fail when applied to the human being.

Dr. Frank Hartley believed that but very little was known regarding the actual processes that were going on and in these instances of bone transplantation one should endeavor to make the graft as nearly like the normal bone as was possible, *i.e.* to take the periosteum along with the bone. One could not get the same results in experiments upon dogs as they could in their work upon the human subject. Macewen's work had been very accurately done and his conclusions were accepted by the general surgeon that they could take the graft from an animal, splitting the periosteum, implant it, and that it would grow. Bone-grafting was comparatively easy so long as they recognized the importance of asepsis. He believed that the essential thing in these cases was the maintenance of the blood supply and this could be better accomplished by leaving the periosteum attached to the bone. The best kind of bone graft was that of Dr. Fred Albee's, cutting a gutter out of the

bone in the medullary cavity and then simply mortising in, bringing the parts in good contact. There would be then a contact of the periosteum with the cortical substance and with the medullary canal.

Dr. Albert Ashton Berg said that he was specially interested in Dr. McWilliams' report as it had brought out the ideas of Macewen, *i.e.* that the bone could be grafted without periosteum attached. The history of these cases had showed what a tremendous and triumphal progress had been made in this work. The function of the periosteum had come more and more into its own. The periosteum was the most important part in transplantation of bone that was to be considered. A very important fact was that in the regeneration of bone certain rules should be followed such as were followed in the growth of bone in its early development in the fetus. Certain deposits were made in the fetus in the center of ossification which extended towards the periphery. At the point of ossification there was a deposition of bone cells which began at the cortex and went toward the center. This was preceded by sprouts which were lined by osteogenetic cells. The younger the animal, or the younger the individual, the more numerous were these osteogenetic cells. Therefore, any experimental work undertaken in young animals would show that the fragments were filled with these osteogenetic cells either in the substance of the bones or beneath. It might be that this applied to the old as well as the young animals. Dr. Berg said that he always endeavored to preserve the periosteum in making transplantations. He had transplanted sections the whole length of the tibia and, on one occasion, the entire humerus. He had much faith in the results of bone transplantation and believed that living, healthy bone would survive.

Dr. Frederic W. Bancroft said that it had been his good fortune to see a great deal of Dr. McWilliams' work and it had been most instructive. His results had been remarkably good. The question of bone growth was one that had bothered histologists and pathologists for years. As they all knew the skeleton was first formed in cartilage it was thought at one time that there was a direct transition of cartilage cells into bone cells. Later the pendulum swung the other way and it was decided that the cartilage cells were destroyed and new bone cells were built up in their places. This was at present the accepted theory, although those who were working in the laboratories admitted that it was a possibility for cartilage cells to turn into bone cells, both being of mesenchymal origin. Then, also the question arose, was it in reality a creator of bone, or did it simply furnish the blood supply to the peripheral bone and tend to conform its shape? During the past year he had been working upon bone repair in the laboratory of Experimental Research of Columbia University and he mentioned briefly some of the results obtained.

Dr. Fred H. Albee said he would like to emphasize some of the statements that had already been made and one was the reliability of the bone graft in the human being. He said he had made as many as 110 bone grafts and 85 of these were for Pott's disease of the spine. Eight were done for ununited fractures. The others were because of deformed feet, etc. With regard to animal experimentation, at the Cornell Medical College, he had been given the opportunity of working during the past two years. He was struck with the fact that these grafts could stand so well when sepsis appeared. Even when the wound became unavoidably septic in grafting the spinous processes there would come out later a sliver, it being sequestrated. In ununited fractures the results had been, in his experience, very gratifying, and he had in mind eight cases in which he had obtained perfect results. In regard to the periosteum he said he did not catch from what the reader of the paper said, whether it was attacked with the blunt or the sharp dissector. They should endeavor to get the osteogenetic cells with the periosteum; then the bone would grow rapidly. With regard to the blood supply he agreed with the statements made by Dr. McWilliams. He recalled one case which was seen seven weeks after implantation, where he found the graft firmly grown in. In another case four weeks after the implant was entered the patient was examined and it was found that it had slipped up and the ends of the bones were not in proper contact.

**Election of Officers.**—*President*, Dr. William M. Polk; *Vice-President*, Dr. L. Emmett Holt; *Trustee* (full term), Dr. John H. Huddleston; *Trustee* (unexpired term of two years), Dr. Wisner R. Townsend; *Recording Secretary*, Dr. Charles F. Adams; *Corresponding Secretary*, Dr. Egbert Le Fevre; *Member Committee on Admissions*, Dr. Linsey R. Williams; *Member Committee on Library*, Dr. Haven Emerson.

*Stated Meeting, Held December 19, 1912.*

The President, Dr. William M. Polk, in the Chair.

This meeting was held under the auspices of the Section on Medicine.

**Resolution.**—This was presented by Dr. Linsey R. Williams, the incoming Chairman of the Section: *Whereas,* It is clearly shown that there is a wide divergence of opinion among physicians, hospital authorities, and nurses concerning the education and training of nurses and also concerning their duties, responsibilities, and status, and *Whereas,* The present system makes the training school also the nursing staff of the hospital, and therefore a peculiarly important factor in hospital administration, and the center of many interests other than educational, thereby causing confusion as to the purposes and functions of the school, and *Whereas,* It is of the highest public importance that the education of this large and necessary body of public servants be properly conducted, and that, for the public good, conditions be removed which are destructive of harmonious and efficient co-operation in this matter between hospitals, training schools, physicians, and nurses, Therefore be it *Resolved*, That this question be referred to the Council of the New York Academy of Medicine, urging that body to co-operate with other suitable agencies in bringing about a full investigation of the entire situation in order that the facts may be ascertained, presented and studied, and made to serve as a basis for remedying existing abuses, for defining and establishing the function of a training school, and for a better adjustment of relationship between training schools and hospitals.

**Some Problems of Nursing; a Plea for Grading.**—Dr. Henry Dwight Chapin read this paper. (See page 93.)

**Some Ways in Which the Hospital Training May Unfit the Nurse for Private Duty.**—Dr. Harlow Brooks read this paper, in which he first called attention to the growing prejudice against the trained nurse in many families and not exclusively those of the least intelligent classes. He said that he had sought to solve this problem, for to his mind this attitude was inexcusable and not justified by the personality of the average nurse. The fault did not lie inherently in the nurse, nor did he believe that it lay entirely with the dissatisfied family. It seemed that perhaps the fault might lie in the preparation of the nurse. One of the most frequent complaints was that the nurse made trouble with the servants or that the servants made trouble with the nurse. One woman had said to him that she could get plenty of trained nurses but that it was very difficult to get an efficient cook or chambermaid. She might have added that it was easier to get plenty of good doctors, for it seemed quite certain that this would be an easier task in New York than to fill the position of a really good cook. There could be no doubt but that nurses were too apt to forget these facts and as a result they might demand too much. One of the most primary qualifications of an efficient nurse in private practice was the ability to adapt herself to varying conditions and to carry out her important functions without producing jar and discord in the household. The hospital training as now conducted did not teach this. The nature of the nurse's work in the hospital was such that she must demand and receive attention and subservience in the wards from the orderlies, scrubwomen, and the like, without thought of their standpoint. The same methods could not be carried out in private practice. In the hospital the nurse was taught to be a commander; in the private family she must be a conciliator, a coaxer, and a consummate diplomat in her relations with the household personnel. Complaints were often registered even in the families of the wealthy that the nurse was wasteful in her use of alcohol, of disinfectants, of drugs, and of dressings. The doctors, themselves, who furnished these things in their offices, were likely to make this same complaint. This unfortunate trait was not due to inherent wastefulness, but was because the nurse was not taught to consider these things in the hospital. It was rare to find a nurse who was familiar with the cost of dressings or of the numerous accessories and conveniences of the sick room. More attention should be paid to instruction in these matters. In the hospital the nurses grew to look upon the patients as "cases," as problems, not as persons. In the private family the case was no longer a patient, but the mother, the son, the daughter, not only whose life, but whose pain and suffering, whose likes and dislikes, were matters of crucial importance. Did the hospital properly equip the nurse to assume this attitude? Perhaps it did if it had a private service, and some training schools had incorporated such a service into their course and their graduates had been

very satisfactory, especially in this important bearing. In private nursing it became necessary for the nurse to prepare articles of apparel or of food; this was true not only of the houses of the poor but also of the rich. It was impossible with the crowded curriculum to teach these things in the training school, but some other subjects might be dropped and these substituted. It would be preferable to have a nurse skilled in the preparation of a sick diet rather than in an intimate knowledge of bacteriology and physiology. There was still another way in which the hospital training might unfit a nurse for private work and in speaking of this he criticized himself and his professional brethren as well as the nurse. In the hospital it was right and proper that cases be discussed *pro* and *con* before the interne and students, that the diagnosis should be continually held in debate, that the treatment should be daily and pessimistically discussed, and that the prognosis should be frankly considered, but nothing more calamitous could be imagined than that the nurse or doctor should enter the private sick room as he or she would enter the public ward and air all the possibilities of diagnosis and prognosis. The doctor soon learned his lesson in this regard; the nurse seemed to learn it rather more slowly. Worst of all was the woman who discussed with the patient or before him those intricacies of previous cases or interesting autopsies which had been witnessed. It would be quite as proper and not nearly as disastrous to incite the public to have their discussions here in the Academy, but he doubted if they could hold their private patients if these heard them doubt and question diagnosis, method, and results as frankly as they did; they would no doubt then prefer the quack who was always right and who needed no consultation. Another point in the hospital training which unfitted the nurse for private work was the division of responsibility inherent and necessary in hospital work. Time and again, a nurse whom he had found thoroughly reliable, accurate in her observations, attentive in attitude, serene and industrious in the hospital accepted her responsibility too lightly in private practice. Most women, however, who seriously took up nursing soon lost this attitude and became sympathetic, conscientious women upon whom one could rely and whom they all admired. Dr. Brooks said he was prepared to say that he would prefer that the nurse should receive less theoretical training in medicine if this must be sacrificed for increased and more valuable efficiency.

**The Training School Problem and Its Solution.**—Miss Sara E. Parsons, Superintendent of Nurses, Massachusetts General Hospital, Boston, Mass., presented this paper, which was read by Miss Clara D. Noyes. She said that training schools for nurses were not doing the greatest good to the community as at present conducted, but that the reasons for this were not easily stated. The problem appeared to be the need of cheap service for the sick public and in the hospitals a sufficient number of suitable applicants for the nursing staff. The fact that pupil nursing had been so satisfactory to the doctors and to the patients where it had been tried appeared to prove that expert nursing was not absolutely necessary in the majority of cases. Nurses themselves who should be the best judges were rightly opposed to this way of meeting the public need because of the injustice to the pupil. A system of grading nurses did not appear, in her opinion, to strike at the root of the defects in their schools. Things had come to such a pass in many of the hospitals that applicants were not available out of which to make any grade of nurses. When they scanned the records of the first schools of training they found a liberal ideal of what a school should be compared with the standards which existed in many of the so-called schools which had been established of late years, and it was not a question of large or small, special or general hospitals, because they found examples of each that were running perfectly successful schools. When schools were first organized it was considered necessary to give the pupils a thorough general training, including medical, surgical, and obstetrical training at least. The success of these schools had been such that hospitals of all kinds regardless of what they were prepared to offer had started so-called schools, and in many instances practically a nonpayment system and a three years' course. Very little account had been taken of the direful consequences of graduating an army of incompetent, dissatisfied women. Were these people after their long years of hard work with no adequate recompense in either money or education going to recommend others to follow their footsteps? They had, through these so-called schools, lost the confidence of the public and this confidence should be restored by making the schools what they ought to be. Not only were the graduates of these so-called schools unfortunate but the public as well, for it was forced to pay graduate charges and was woefully humbugged. When hospitals changed from the old system of paid attendants to pupil nursing they assumed an educational responsibility in place of a business arrangement. Some hospitals met it more fairly than others and their schools had deservedly won good reputations. These were not the schools that were complaining of the nursing situation. Injustice had unconsciously been done the nurse owing to the traditional idea that hardship was an indispensable part of a nurse's life. It was the belief of the speaker that before the nursing situation could be any better the hospitals would have to reform their nursing system effectually by searching out the fault in each system and doing what was needful at any cost. There was no justice in doing charity for some at the expense of others, nor in spending time and money alleviating pain and poverty while deliberately impoverishing the physical resources and professional efficiency of another class. The effects of false standards in relation to nursing work could be seen in some of the European countries. In some countries the popular sentiment was so against a living remuneration that it was a long and desperate struggle for the nurses to wrest themselves from the mother houses and to win proper training and a living wage. The day had come when they saw the folly of work done under religious enthusiasm and without practical thought of its worth or the ultimate effect upon the community that permitted it. Hospitals must face the necessity of regulating their affairs after ordinary business methods in relation to the nursing department and there were two alternatives—financial or educational equivalent for services rendered. The minimum educational requirement for the kind of nursing that was demanded today was a full high school course or a good equivalent, with an elementary knowledge of Latin, chemistry, anatomy and physiology, and bacteriology. Given this foundation the hospital could build upon it a consistent structure of theory and practice that would produce satisfactory results. The pupil who knew less than was indicated above was a dangerous person to intrust with drugs or diets as now prescribed. It was possible for both high school and college graduates to fail dismally at nursing as tact and common sense were absolutely essential in the successful nurse. The college woman needed as much practical experience in nursing as the less educated woman since she had always been a student and had not learned to use her hands, or to put her theory to practical use. When one considered the ground to be covered the three years' course was none too long. As to those who needed trained attendants, there was a class of women who could never qualify as trained nurses who might make invaluable attendants where no resopsibility must be assumed. Such women might be trained in elementary nursing and domestic science and certified to work as "attendants" or "home halpers." The training schools might train such a class of workers. This solution would be simpler than grading nurses.

**The Efficient Nurse.**—Mrs. C. V. Twiss, president New York State Nurses' Association, read this paper, which she said she supposed she had been asked to present because she was the presiding officer of the New York State Nurses' Association. During the past eight years she had been continuously an officer of either her alumnæ, the County, the State, or the National Association, and was therefore familiar with the feelings and opinions of a large majority of the members of these associations. The strongest desire of these women as a body was to improve their efficiency in every possible way, not for the benefit which might accrue to them financially, but that they might be of greater service to the sick and dying upon whom they were called to minister. The nurse of to-day was no more the nurse of the olden time than the doctor of to-day was the doctor of fifty years ago. It was her belief that the nurse should strive to increase her efficiency and to improve her methods of work, just as the doctor was doing. The fact should be emphasized that in order to increase her efficiency the nurse should possess certain qualifications other than those with which she was naturally endowed. It went without saying that the doctor and nurse should have certain natural capacities for their work. It was possible for a man to become a good doctor without a college education, but such a course was intended to make him a better one, and likewise a woman might become an efficient nurse without a high school education, but she should somehow be in possession of the knowledge she would acquire in such a school. It had been stated by members of the medical profession that the nurse of the present time was too highly trained and the proposal had been made to encourage persons who had less education to enter the training schools for nurses, that provision be made by these schools for courses of one or

two years, and that these persons be called trained attendants. The drudgery that should be delegated to maids was discouraging to the student and unfitted her for study and it was no more reasonable to expect women entering training school to perform such work than to expect the medical student to perform the duties of watchman, coal-heaver, etc., because the hospital could not afford to pay men for such work. Under present conditions a three years' course was none too long to impart the instruction that was necessary to graduate an efficient nurse. The ramifications of medical and surgical treatment were becoming more and more extensive and both doctor and nurse should be able to cope with any case to which they were called. There was but one medium of values in their profession and but one standard of efficiency and that was represented by a diploma from the proper authorities. Upon this diploma rested their authority to do the work they had chosen and the guarantee to the public that the work would be well done. It was to be hoped that the day would come when the State of New York would require every woman practising the profession of nurse to be registered and then the title of R. N. would have a definite meaning, whereas to-day it was merely a complimentary honor. A point which should be emphasized was that this greater efficiency of the nurse was in the interest of the public. This would not be accomplished by establishing a double or triple standard of efficiency in the nursing world. If the physicians were handicapped in securing the services of nurses at prevailing prices it might be well to look into the manner of living of one's patients and see if their objection to paying the price was not due rather to penuriousness than to lack of means. If it was found that the supply of nurses was not keeping up with the demand then it might be a wise plan to induce the hospitals to make it more attractive for women to seek admission to their training schools. The necessity of placing instructors of the highest ability at the head of training schools should also be urged. The most essential thing in regard to the problem of the trained nurse was the cooperation of the doctor and the nurse. Such meetings as this should tend to bring them into closer sympathy for one another's work and thus increase the nurse's efficiency and give the public the best service.

**The Need of Orientation.**—Miss Anna W. Goodrich, inspector of Nurse Training Schools, New York State, presented this communication, in which she emphasized the importance of the determination of one's position in relation to new environment, or new ideas, or concepts. One should have an exact conception of the act of nursing, and especially attempt to determine one's true position in relation to nursing.

Miss Clara D. Noyes, superintendent of nurses of Bellevue and the Allied Hospitals, said that no one was more keenly alive to the defects of the present method of preparing pupils for the field of nursing than those who had dealt with these problems first hand in the training schools and institutions for the care of the sick. It was a big problem and was not confined to New York City. It was a question which concerned the future of hospitals, of private nursing, and of all social and public health work. The nurse had become one of the most important social and economic factors in the community, and, therefore, the problem was not one that could be disposed of hurriedly, but one which required profound thought and deliberation. The organized bodies of nurses had been giving these problems attention for years and although much had been done to improve the schools of nursing the work was only just begun. Conditions had changed in the training schools for nurses as elsewhere. The same feeling of unrest which had attacked all walks of life was felt just as keenly in their schools and hospitals. Medical schools were not managed in the same way as in the past, nor did physicians do their work as it was done thirty years ago, neither could schools of nursing be continued in the same way. Hospitals found it almost impossible to secure suitable women for their many important positions, while social service, district nursing, public health, and school nursing were clamoring for the highly educated, well prepared nurse. At the same time the community was filled with unprepared women, the product of a lowered standard in the training school, of correspondence courses, etc. Many of these have never had any actual experience or hospital training, and therefore it did not seem that there should be any reason why a cheaper grade of sick room helper should not be available. In order to correct these evils laws had been enacted in nearly all the states; that of New York demanded a minimum educational qualification of one year in high school, or its equivalent, as the entrance requirement of a registered school. Some states required a much higher educational standard. It was a significant fact that in those schools where the educational qualification was high and the school conducted on an educational basis, where shorter hours prevailed, even if an entrance fee was demanded, there seemed to be no scarcity of applicants. Miss Noyes maintained that they must adhere to the law as it stood in New York State, otherwise the hospitals would gradually revert to the condition in which Florence Nightingale found them. The practical difficulties in the way of the plan advocated by Dr. Chapin were: that there would have to be separate nurses' residences; there would be a prohibitive staff of paid supervisors; instead of three classes of nurses, there would be required three classes of the three-year students, two classes of two-year pupils, and two of one-year pupils —seven separate and distinct classes to be housed, fed, supervised, and instructed, and at the termination of the various courses there would be no way for the public to distinguish a one-year nurse from a three-year nurse. Moreover, it would only be a short time before the well-educated, higher type of woman would cease entirely to enter the school. Why should the highly educated woman be required to spend three years in a hospital, bear all the responsibility, and take all the night duty, while her ignorant sister was required to take but one year? A supplementary force of ward maids introduced into the wards at Bellevue had proved a failure as far as any assistance with the actual nursing and care of the patient was concerned; this might in a measure be due to the class of women who had been willing to try the work. They had, however, a distinct value when restricted to domestic work, thus releasing the pupil nurse for actual nursing duties. They had found it unsafe to entrust to these helpers the simple duty of dusting the bedside table. If a nurse was needed at all, the finest type of skilled worker was the one required. If such a nurse was not needed, probably a well-trained domestic worker would serve the purpose, but she should not be trained at the expense of the nursing profession and under the protection of the word "nurse" be permitted to practise upon the unsuspecting public, neither should the hospital training schools be asked to train this type of domestic servant for a community. Miss Noyes said that during her twelve years' experience in conducting registries in connection with hospitals in different cities, physicians and laity invariably emphasized the fact that they wanted not only a trained nurse, but a well-bred, refined woman. It became more and more difficult to interest nurses in private nursing, and there might be a reason for this. There also seemed to be a lessened demand at Bellevue and the Allied Hospitals, while inquiries for institutional positions from women who were willing to do actual hard work had increased. Out of a class of 34 graduated at Bellevue this year, 23 were filling institutional positions. The best interests of the public, the hospital, and the nurse would be served by schools established upon a sound educational basis determined by law, with State inspection of schools and hospitals, and by compulsory registration of graduate nurses.

Dr. S. S. Goldwater, superintendent Mt. Sinai Hospital, said that it was true that similar conditions regarding the trained nurse were met with in hospitals as were met outside of them. He did not believe in hospital administration with nurses responsible. In hospitals administration was performed by the older members of the nursing staff. Originally all the instruction was given by the principal of the school and voluntary members of the medical staff, but more progress had been made by organizing under the present State law regarding the instruction of nurses in training schools. In regard to Dr. Chapin's proposition to have first, second, and third degree nurses, he asked to what extent the graduate nurse of higher type would be called for, and also whether any considerable number of training schools could be maintained on that basis. He thought it was a mistaken argument, because the training schools in such cities as Boston, Baltimore, and New York showed that the general application of such a policy was the practical thing. He doubted whether such a policy as outlined by Dr. Chapin could be used with success. However, if they moved too hastily in this matter it would be a mistake for it might happen that much of the sick nursing would be done by those who were not nurses at all. He advised them to be cautious and said that whatever was done should be done in a series of slow but progressive steps.

Dr. John A. Hartwell said that the practical question was, what was the best to be done for the sick and needy who did not go to the hospitals and could not afford to pay what a properly trained nurse asked for. The sick were among them and must be cared for. Medical education throughout the country had persistently increased the demands made upon the medical man, and the standards

had been raised and by those who had the interest of the public and the profession in mind. He did not see why the same rule should not apply to the trained nurses. Personally he preferred to have on a case the best trained nurse of the highest type of mind that could be procured. He believed there would be great danger in adopting two grades of nurses, for soon the second grade would become the first grade. If 12,000 women in this State received diplomas through correspondence schools during a year they would deceive the public.

Miss ADELAIDE NUTTING said she would like to throw light upon one point that had been overlooked regarding the high-priced nurse. The nurses to-day were charging the same as they charged twenty-five years ago; although the cost of living had increased, they would find that the trained nurse did not charge more than $25 a week. The nurses supposed to have graduated from the correspondence schools seldom received as little as $18, and usually $25 a week for her services.

**Election of Officers.**—*Chairman*, Dr. Linsey R. Williams; *Secretary*, Dr. J. C. Roper.

# State Medical Licensing Boards.

## STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS, STATE OF GEORGIA.

*May*, 1912.

(*Concluded from page* 45.)

### DISEASES OF CHILDREN.

1. Etiology, symptoms, and treatment of lobar pneumonia?
3. Differential diagnosis between lobar and bronchopneumonia?
4. Symptoms, cause, and management of poliomyelitis?
5. Symptoms and management of scarlet fever?
6. What is the danger of allowing a child to lie in one position when suffering with a protracted illness?
7. Etiology, symptoms, and treatment of cholera infantum?
8. Symptoms and treatment of diphtheria?
9. Difference between spasmodic and true croup; treatment of each?
10. Differential diagnosis between variola and varicella?

### OBSTETRICS.

1. Define postpartum hemorrhage; state causes, varieties, and give treatment.
2. How would you manage a brow presentation?
3. Give the diagnosis and treatment of hour-glass contraction of the uterus.
4. What is placenta prævia? Give varieties, symptoms, dangers, and management.
5. When is curettage of the uterus justifiable in obstetric practice, and how should it be performed?
6. Give indications for and methods of terminating pregnancy prematurely.
7. Describe the fetal circulation.
8. When and how is a repair of lacerated cervix to be performed? Of lacerated perineum?
9. What are the dangers of traction on the cord?
10. Discuss the use of anesthetics during labor.

### GYNECOLOGY.

1. Describe the female reproductive organs.
2. What is meant by plastic operation? Describe operation for perineorrhaphy and trachelorrhaphy.
3. Define caruncle of urethra and give treatment.
4. When would you use the curette? Give steps of the operation in detail.
5. What is a pelvic hematocele? Give etiology, diagnosis, and treatment.
6. What is vicarious menstruation?
7. What are Skene's glands? Give the signs of their inflammation.
8. Describe ventrosuspension and ventrofixation. Under what conditions may either operation be justifiable?
9. Give treatment of inevitable abortion.
10. Give treatment of cystitis.

### SURGERY.

1. What is aneurysm? Differentiate between true and false sacculated aneurysm. With what conditions may aneurysm be confounded? Differentiate between abscess and aneurysm.
2. Name the inflammatory diseases of bones. How should a case of acute suppurative osteomyelitis be treated? What is a fracture? What is a dislocation? Differentiate between fracture and dislocation. Name the two essential principles in treatment of fracture.
3. What are the symptoms of fracture of the spinal vertebræ with pressure? Give symptoms of traumatism of about the ninth dorsal vertebræ in which the cord is entirely severed; partially severed. Under what conditions would an operation be indicated and under what conditions would it be contraindicated?
4. Differentiate between scrotal hernia and hydrocele. What is hernia? How should strangulated oblique inguinal hernia be treated? Describe an approved operation for the radical cure of an oblique inguinal hernia.
5. What is a tumor? What is an adenoma? What is an angioma? Describe a dermoid cyst. Give indications for the removal of the mammary gland.
6. How should a dissecting wound and attendant blood poisoning be treated? What is the rational treatment of a suppurative abscess from its initial symptom? Give symptoms of psoas abscess. With what conditions may it be confused?
7. Define epispadias, hypospadias, phimosis, and paraphimosis. What are the more frequent causes of phimosis? Give treatment briefly.
8. Name the most common varieties of fistula. Describe briefly an operation for fistula *in ano*? Describe an approved operation for the removal of hemorrhoids.
9. What is shock and how treated? What agents are preferable for the production of general anesthesia? What are the contraindications to the use of the three principal general anesthetics?
10. Give differential diagnosis of coma from injury, opium poisoning, apoplexy, uremia, and alcoholic intoxication. Describe septicemia; pyemia. Give differential diagnosis.

## ANSWERS.

### DISEASES OF CHILDREN.

1. LOBAR PNEUMONIA. *Etiology:* The *diplococcus pneumoniæ*. *Symptoms:* Short incubation period, chill, convulsions, rapid rise of temperature, localized pain, the pulse-respiration ratio is altered, being reduced from 1:3.5 to 1:1.5, rapid respiration, rusty sputum, flushed face, headache, rapid pulse, herpetic vesicles round the mouth, dilated pupils, dry tongue, and crisis between fifth and eighth day. *Treatment:* Rest in bed; ample ventilation; milk and other fluid diet; leeches or blisters for the pain; cold sponging and quinine for the fever; ice-bags, bromine, and Dover's powder have been found useful.

3. See PRACTICE, question 2.

4. POLIOMYELITIS. *Symptoms:* "The onset of the affection varies; it may be acute, subacute, or chronic; it is usually sudden, with an attack of mild fever of a remittent type, of a few days' duration, on recovery from which it is noticed that the child is paralyzed. Rarely the paralysis may be preceded by convulsions. The paralysis may affect both arms and both legs, the legs alone, or only one of the four extremities; it may, very rarely, be a hemiplegia. As a rule, however, the leg suffers more frequently than the arm; in paralysis of the leg the muscles below the knee suffer more severely than those above. The bladder and rectum are not affected, or, if so, only temporarily, and anesthesia or numbness cannot be detected. The temperature of the paralyzed limb is low and the part is cyanosed in appearance. After a few days there is a slight improvement in the paralyzed parts, although the muscles show a rapid wasting, which is progressive until all muscular tissue is gone. The reflex movements are impaired or abolished. The electro-contractility by the faradic current is abolished in the paralyzed parts. With the galvanic or constant current the 'reactions of degeneration' are developed." (Hughes' *Practice of Medicine.*)

*Treatment:* "During the febrile stage the patient should be placed at rest in bed and all the secretions rendered free. If the affection is suspected at this period the limbs should be wrapped in cotton-wool and ergot administered to lessen the spinal congestion. Counterirritation is unnecessary. As soon as the febrile reaction has subsided and the paralysis becomes manifest the child should be well fed and taken outdoors once daily. Gentle friction should be applied to the affected muscles at first, followed later by the hot spinal douche and mild galvanism. Internally, quinine, belladonna, ergot, and potassium iodide may be of value. Later, as improvement takes place, tincture of nux vomica, ♏i to iii, three times daily, or

hypodermic injections of strychnine sulphate, gr. 1/100 to 1/16, according to the age, twice a week, and faradism to the paralyzed muscles, are to be used. Means should be taken to prevent deformities." (Hughes' *Practice of Medicine.*)

The disease is probably caused by a microorganism which has not yet been identified.

5. SCARLET FEVER. *Symptoms:* Sore throat, high fever, vomiting, headache; rash, appearing on first or second day, first on chest, then on face, body, and extremities, is scarlet and punctuate; "strawberry tongue," enlarged glands at angle of jaw; desquamation in branny scales or in flakes. *Treatment:* This "consists first in isolation until desquamation has been completed. The patient should be placed in bed and liquid diet should be prescribed. The room should be well ventilated and all unnecessary furnishings should be removed. A sheet wet with some antiseptic solution should be hung over the doorway, and attendants should be covered with long gowns to prevent carrying the infection in their clothing. Careful disinfection of the hands, face and hair is absolutely necessary on the part of the physician, nurse, and other attendants. The throat and nose should be cleansed by some alkaline or antiseptic solution, such as Dobell's, peroxide of hydrogen, or sodium bicarbonate solution. The throat symptoms may be relieved by the inhalation of vapor containing eucalyptus oil, turpentine, etc. The gastrointestinal disturbance will require the use of calomel, and the vomiting may be controlled by small pieces of cracked ice, paregoric (gtt., 1-5), or cocain (gr. 1-20). Acetanilid (gr. ½ for each year of age), phenacetin, or quinine (gr. ½-1) will relieve the nervous symptoms. If the pulse becomes weak and the heart irregular, stimulants, such as aromatic spirits of ammonia (gtt. 10), brandy or whisky (gtt. 10), strychnine (gr. 1-100 to 1-30), nitroglycerine (gr. 1-500 to 1-100), etc., are indicated. Daily sponging with antiseptic solution and inunctions with cacao-butter are very beneficial." (*Pocket Cyclopedia.*)

6. Bedsores.

7. *Cholera infantum* is caused by bacteria or their toxins in milk.

*Symptoms:* Diarrhea is the initial symptom. The stools are more or less fecal, but soon become watery, colorless, and odorless. In some cases they may be of a brownish-green color with a musty odor. There are restlessness, high fever (105-108° F.), thirst, vomiting, and purging. The child rapidly wastes, and the surface temperature falls. The urine is scanty or suppressed, and the child becomes apathetic, which condition may pass on to convulsions, stupor and death.

*Treatment:* Ordinary diarrhea should be prevented from terminating in cholera infantum. The stomach and colon should be irrigated. From ℥2-4 of water at 100° F. should be allowed to flow into the stomach through a soft-rubber catheter and be siphoned out. This should be done only once. For the colon, sodium bicarbonate, ʒi, should be added to the pint, and the irrigation performed twice daily. If the rectal temperature is very high ice-cold water should be used; otherwise warm water. When symptoms of collapse appear hot pack is used. Ice-water quenches the thirst, even if it is vomited. Champagne and drop-doses of brandy may be given if the stomach is tolerant. Strychnine, gr. 1/100 hypodermically, to a child one year old, is a valuable stimulant. Morphine, gr. 1/100, and atropine, gr. 1/800, may be given in the same way and repeated every hour until the child is quieted. (*Pocket Cyclopedia.*)

8. *Symptoms of diphtheria:* General malaise, slight fever, stiff neck with swollen glands, congestion of fauces and soft palate, white patches in throat, which coalesce and form the false membrane; anemia, weakness and rapid pulse; and see PRACTICE, Question 6. *Treatment:* See PRACTICE, Question 6.

9. *Membranous or true croup* is either laryngeal diphtheria or a streptococcus infection. In either case there is a prior stage of malaise, accompanied by chills, fever, and sore throat. The fever may become very high. A membrane forms, in which are found the Klebs-Loeffler bacillus or streptococci. *False or spasmodic croup* generally comes on suddenly, at night. There is no appreciable fever, no previous malaise or sickness, and often the patient is asleep again by the time the physician arrives. There is frequently a thick tenacious mucus, but neither Klebs-Loeffler bacilli nor streptococci are present. It is entirely a local disturbance.

*Treatment of true croup* is practically the same as for diphtheria at the commencement; see PRACTICE, Question 6. In addition, tracheotomy may be necessary. For *false croup*, the child should be put in a warm bath; wine of ipecac, or other emetic, should be administered; calomel, in divided doses, may be given; diet should be fluid, and restricted; steam and tincture of benzoin may be inhaled. Intubation or tracheotomy may be necessary.

10. *Variola and varicella:* (1) Very young children are attacked with varicella, whereas variola usually shows itself in dults. (2) Vaccinated children readily take varicella; not so variola, even in the modified form. (3) Children who have had varicella may contract variola, even soon afterward; or the two diseases may coexist. (4) Varicella is not inoculable, whereas variola is notoriously so. (5) The eruption of varicella appears in twenty-four hours; that of variola not till the third day. (6) The febrile symptoms continue after the eruption appears in varicella; those of variola subside. (7) In varicella the spots come out in successive crops; this is never seen in variola. (8) The spots in varicella are unilocular, and collapse on being punctured; the spots in variola are multilocular, and do not collapse on being punctured. (9) In varicella the eruption is very irregular, and appears over the body generally; in variola it appears in groups of threes and fives, and is always seen on the limbs. (10) The papule in varicella is soft, and disappears on stretching the skin; in variola it is hard and shotty, and does not disappear on stretching the skin.

OBSTETRICS.

1. *Postpartum hemorrhage* is a hemorrhage occurring from the uterus or birth canal within six hours after delivery. *Causes:* Lacerations to birth canal, rupture of veins, failure of uterus to contract, and retention of placenta or clots. *Varieties:* Primary and secondary; traumatic and atonic. *Treatment:* Grasp the uterus at once, through the abdominal wall, and massage it firmly. Anything in the uterus should at once be cleaned out. Pass one hand into the uterus, and with the other on the outside make firm pressure. A hypodermic of ergotin, or ergol can be given by an assistant. An intrauterine douche of hot sterilized water (about 115° F.) may be given. Sometimes a very thorough packing and plugging of gauze of uterus and vagina may be necessary. Whatever is done must be done promptly; and everything likely to be needed for this emergency should be prepared beforehand in every labor.

2. *Management of brow presentation:* If recognized before the onset of labor, postural treatment may be tried. This consists in placing the woman on that side toward which the fetal face is directed, so as to secure flexion of the fetal head. Failing in this, or if only recognized too late for the above to be tried, cephalic or podalic version may be attempted; or forceps may be applied, chiefly to act as a rotator. If the above do not succeed, symphyseotomy may be performed, and the child delivered by forceps. When all other methods fail, if the child is dead craniotomy is indicated.

3. *Hour-glass contraction of the uterus* is *diagnosed* by introducing the hand into the uterus and finding a constriction below the placental site but well above the internal os, and feeling something like a second internal os. *Treatment:* Insert the fingers and then the hand within this constriction, and so overcome its resistance. An anesthetic should be given.

4. *Placenta prævia* is the condition in which the placenta is attached in the lower uterine segment, and may be near or over (partially or completely) the internal os. *Varieties:* (1) *Central*, when the placenta completely covers the os. (2) *Partial*, when the placenta overlaps the os. (3) *Marginal* or *lateral*, when the placenta reaches the margin of the os but does not overlap it. *Symptoms:* Sudden hemorrhage, accompanied by syncope, vertigo, restlessness, and feeble pulse. *Dangers:* Hemorrhage, sepsis, death of the mother, death of the fetus. *Treatment:* Stop the hemorrhage by a vaginal tampon; this must be tight and thorough. *Accouchement forcé* is indicated; this consists of dilatation of cervix, version, and immediate extraction of the child.

5. See GYNECOLOGY, Question 4.

6. Conditions that justify the induction of premature labor: (1) Certain pelvic deformities; (2) placenta prævia; (3) pernicious anemia; (4) toxemia of pregnancy; (5) habitual death of a fetus toward the end of pregnancy; (6) hydatidiform mole; (7) habitually large fetal head. The methods that may be employed are: Partial dilatation of the cervix and the introduction within the cervix (and vagina) of a tamponade of sterile gauze; (2) dilatation of the cervix; (3) puncturing the membranes; (4) introduction of a soft rubber bougie into the uterus; (5) intrauterine injection of glycerine, water, or some other fluid.

7. *The fetal circulation:* "The arterial blood coming

from the placenta to the fetus travels along the umbilical vein to the liver. After giving off several branches to the left lobe it divides into two streams, the larger joining the portal vein and thus entering the liver, the smaller passing directly into the inferior vena cava through the *ductus venosus*. In the inferior vena cava the blood carried by the hepatic veins and ductus venosus mixes with the blood which has circulated through the lower extremities. On entering the right auricle the blood of the inferior vena cava is directed by the Eustachian valve, through the foramen ovale into the left auricle, and from thence into the left ventricle. The left ventricle forces it into the aorta, and it is then distributed to the head and upper extremities, a small quantity only passing into the descending aorta. The blood which has circulated through the head and upper extremities returns to the heart along the superior vena cava, the blood then passing into the right ventricle and pulmonary artery. A small part of the blood in the pulmonary artery is conveyed to the lungs, but the major part passes through the ductus arteriosus into the aorta at the commencement of the descending portion. This blood is distributed to the lower extremities, a certain portion of it entering the hypogastric arteries and being conveyed to the placenta." (Ashby's *Physiology*.)

8. See GYNECOLOGY, Question 2.

9. *Dangers of traction on the cord:* Premature detachment of the placenta; partial removal of placenta, with pieces left behind; this necessitates manual removal; inversion of uterus; sepsis.

10. ANESTHETICS are used in labor to lessen suffering produced by labor pains; to lessen the pain attending obstetric operations; to relax the uterus when its rigid contraction interferes with version; to promote dilatation of the os uteri; to reduce excessive nervous excitement which may interfere with progress of early stage of labor; to relieve eclamptic convulsions and mania; in cases of uterine inversion to relax the constricting cervix and so facilitate replacement; in bipolar version to lessen pain of introducing the hand into vagina; in precipitate labor to suspend action of voluntary muscles and retard delivery; in all cutting operations upon the abdomen; and sometimes in sewing up a lacerated perineum when many sutures are required. (From *King's Obstetrics*.)

GYNECOLOGY.

1. In the nulliparous adult the *uterus* is about three inches long, about two inches wide at the upper part, and about one inch thick. The uterus lies between the rectum behind and the bladder in front; it is below the abdominal cavity and above the vagina. Its position is one of slight anteflexion, with its long axis at right angles to the long axis of the vagina. The anterior surface of its body rests on the bladder, and the cervix points backward toward the coccyx. The uterus is not fixed, but moves freely within certain limits. It is held in place by ligaments—broad ligaments, round ligaments, vesicouterine, and rectouterine.

The *Fallopian tubes* are about 4½ inches long, and extend from the cornua of the uterus outward to the free surface of the ovary. The lumen of the tube is much greater at the ovarian end than at the uterine end. At the outer end it is surrounded by fringed processes called the fimbriæ. It lies at the upper edge between the two layers of the broad ligament.

The *ovaries* are almond shaped, about 1½ x ¾ x ½ inch; they are attached to the posterior layer of the broad ligament, at the outer end of and a little below the Fallopian tube.

2. *Plastic operations in gynecology* are such as are done: (1) for the repair of lacerations of the perineum or cervix; (2) for vaginal fistulæ; (3) for the narrowing of the vagina, and the treatment of cystocele or rectocele; and (4) various other operations on vulva, urethra, or anus.

*Perineorrhaphy:* "The labia are seized with Allis' forceps at the level of the lowest carunculæ myrtiformes. A guide stitch is placed in the posterior vaginal wall directly under the external urinary meatus. By pulling one Allis forceps and the guide stitch in opposite directions outward and downward, the posterior sulcus is exposed; denudation is required, even in a recent tear, for a part of it is always submucous. The other sulcus is exposed and denuded. Then by holding the guide stitch upward in the middle line and pulling the forceps apart the mucous membrane between the sulci is denuded or freshly torn surfaces covered with granulation-tissue are scraped with the edge of a knife. The ruptured levator ani muscle in the posterior sulci is united with a double tier suture of chromic gut, two half-hitches being taken in the stitch as it turns upward after coming down from the apex of the wound, in its deeper portion to the base. One knot at the apex of the sulcal denudation secures the stitch. The retracted ends of the transversus perinei and bulbocavernosus muscles are brought together by silk-worm sutures. Finally, a single stitch at the top of the perineal wound unites the posterior commissure of the vulva, restoring the fossa navicularis. The perineal stitches are knotted; they are removed on the twelfth day." (Hirst's *Obstetrics*.)

*Trachelorrhaphy:* "For trachelorrhaphy the two lips of the cervix are seized with double tenacula and pulled down, an Auvard's speculum retracting the posterior vaginal wall. Denudation is resorted to if necessary. The raw surfaces are united with interrupted sutures of chromic gut. Care must always be exercised to leave a wide cervical canal. For amputation of the cervix, which is required when the injury or sloughing leaves a condition irreparable by plastic surgery, a circular incision is made above the site of the injuries and the cervix is amputated in healthy tissue. The sutures of chromic gut are inserted according to the modified Hegar plan." (Hirst's *Obstetrics*.)

3. *Urethral caruncle* is a small red fleshy growth generally situated on the posterior part of the meatus of the urethra. There are local pain and tenderness, which may be excessive; a burning sensation is experienced on urination; it may bleed. The proper treatment is to excise it or destroy it with the thermocautery.

4. CURETTAGE. *Indications:* For diagnosis: to remove pieces of retained placenta or decidua; in cases of endometritis, mucous polypi, hemorrhage, dysmenorrhea, endocervicitis. *Dangers:* Sepsis, perforation of uterus, hemorrhage, abortion, inflammation of uterus or adnexa. *Procedure:* All antiseptic and aseptic precautions are necessary, the patient should be in the dorsal position, the vagina is to be disinfected, and the cervical canal dilated; a speculum is introduced into the vagina and the cervix is drawn down with volsella; the uterine cavity is irrigated with creolin or lysol; a curette is inserted to the fundus and moved down to the internal os; the operator should begin at one cornu, and go in the same direction all around till he reaches the starting point, and if necessary repeat till no more spongy or hyperplastic tissue appears; the fundus should be scraped separately by moving the curette along it from side to side; in going towards the fundus no scraping should be done, and care must be taken not to perforate the uterus; should this happen no fluid must be injected; otherwise the uterus and vagina are again irrigated, and one or more strips of iodoform gauze are inserted into the cavity to act either as a hemostatic plug or as a drain, which is diminished with two days' interval and withdrawn on the sixth day. A hemostatic tampon should be placed in the vagina and withdrawn the following day. If any fever arises the tampon is at once removed and the vagina douched with antiseptic fluid every three hours. If not, the vagina is only swabbed with the same every day, and packed loosely with iodoform gauze. After the final removal of the gauze the antiseptic douche is given twice a day until there is no more discharge. The patient should remain in bed for a week.

5. *Pelvic hematocele* is an accumulation of blood in the pelvis, due to rupture of a blood-vessel; it is generally due to rupture of a tubal pregnancy, or to a tubal abortion, or disease of the ovary, or perimetritis. *Symptoms:* Pain, which is sudden and severe, over abdomen and pelvis; nausea, cold perspiration, cold extremities, pulse rapid and weak, pinched features, and shock. It is most likely to be mistaken for an ectopic gestation; but in the latter there will have been the subjective symptoms of pregnancy.

*Treatment:* Removal of the blood and diseased tube or ovary. This may be done by the vaginal route or by the abdominal route.

6. *"Vicarious menstruation* is a flow of blood from some organ (other than the uterus), recurring at the monthly periods and taking the place of menstruation. It may occur from the hemorrhoidal vessels, the lungs, the skin, the nails, the mammary glands, ulcerated surfaces, and many other parts." (King's *Manual of Obstetrics*.)

7. *Skene's glands* are two small glandular tubules, about half an inch long, situated in the mucous membrane of the female urethra; they open by small ducts just within the meatus. When they are *inflamed* they emit a serous or purulent discharge; the mucous membrane is swollen and thickened, and the orifice may be surrounded by a small granulation area. Pressure causes pain.

8. *Ventrosuspension.* "An incision is made through the

abdominal wall in the median line just above the symphysis pubis and extending upward for a distance of two inches. The index and middle fingers of the left hand are passed into the peritoneal cavity and gently inserted between the uterus and the rectum. The adhesions are then carefully separated and the fundus of the uterus lifted forward into its normal position. The peritoneum at the lower angle of the wound is seized with hemostatic forceps and drawn into the incision and the first suspension suture introduced close to its divided edge on the left side. The index and middle fingers of the left hand are then passed into the abdominal cavity and the uterus securely held while the suture is passed through the fundus. The suture is now introduced into the fundus directly on a line dividing the uterus transversely into two equal halves and buried one-quarter of an inch deep in the uterine tissue with a distance of about half an inch between the points of entrance and exit. The uterus is then released by the fingers of the left hand and the suture passed through the peritoneum opposite to its point of entrance. The second suture is now passed through the peritoneum on the left side one-quarter of an inch above the first suture. It is then passed through the fundus about one-quarter of an inch behind the first suture, and finally through the peritoneum opposite to its point of entrance. It is not necessary to hold the fundus between the fingers while the second suture is introduced, as the uterus can be easily controlled by making traction upon the free ends of the first suture. After both sutures have been introduced their free ends are seized with forceps and placed on each side of the abdominal incision. The through and through sutures closing the abdominal incision are introduced and suspension sutures tied. The first three sutures closing the incision at the lower angle of the wound must be introduced so as to pass completely under the peritoneum at its points of attachment with the fundus, otherwise the weight of the uterus will cause stripping and a large dead space will result which will eventually become filled with serum or blood and suppurate. After all of the incision sutures are introduced the suspension sutures are drawn taut so as to take out the slack and bring the fundus of the uterus up against the peritoneum. The sutures are then tied and their free ends cut off close to the knots. The abdomen is closed and the wound dressed in the usual manner. The fascia is first united with a continuous suture of catgut and the wound then closed by tying the through and through sutures. The sutures in the lower angle of the wound are tied first, and special care must be taken to remove the slack and bring the peritoneum, at its points of attachment with the fundus, snugly against the abdominal wall." (Ashton's *Gynecology.*)

*Ventrofixation.* "This is a procedure that must be cautiously undertaken in married patients who have not reached the climacteric. An incision two or three inches in length is made immediately above the symphysis, and the fundus uteri is drawn forward by a volsellum. The silkworm gut stitches are inserted through the abdominal parietes and peritoneum, and also through the body of the uterus just posterior to its axis. The stitches should include about three-quarters of an inch of the uterine wall in their grasp, and go about one-eighth of an inch deep. On drawing them tight, the uterus is fixed forward against the abdominal wall and contracts adhesions. In some cases it may be desirable to scarify the uterine wall before tying the stitches, so as the better to determine adhesions. As a general rule the adhesions stretch somewhat, and hence allow a certain degree of play, but without the likelihood of a return of the displacement." (Rose and Carless' *Surgery.*)

*Ventrofixation* is indicated in cases of prolapsed uterus uncomplicated by uterine tumor, and when subsequent pregnancy is not expected to occur.

9. *Management of inevitable abortion:* "Two methods of treatment have been advised for these cases. The first is the *expectant plan:* Place the patient in bed, and if the bleeding is profuse insert a tampon of iodoform gauze (one yard) well up against the cervix. If this fails to control the hemorrhage, reinforce it by another yard or two of gauze and a perineal pad and binder. Small doses (3½) of the fluidextract of ergot should now be given every two or three hours. At the end of from eight to twelve hours remove the tampon, when the ovum may be found extruded from the cervix; if not, a vaginal douche of mercuric chloride (1:4000) must be given, and another tampon introduced. If, upon the removal of this second tampon at the end of ten or twelve hours, the ovum is not discharged, then more vigorous methods to secure its expulsion must be adopted. *Active plan:* The physician's hands and instruments are sterilized; the patient is etherized and placed on an appropriate table; the genitalia are thoroughly cleaned and a vaginal douche of mercuric chloride (1:4000) is given; the anterior lip of the cervix is brought down to the vulvar orifice; the cervix is dilated if necessary; the placental forceps is introduced into the uterus, and as much as possible of the ovum is removed; the uterus is thoroughly curetted, and an intrauterine douche of sterile water is given. A light tampon of iodoform gauze is placed in the vagina; the patient is then returned to bed. A strip of gauze may be placed in the uterus in cases of sharp retroflexion, to secure free drainage, and occasionally an intrauterine tampon will be necessary, when the uterus refuses to contract and hemorrhage persists after the use of the curette." (Gould & Pyle's *Pocket Cyclopedia.*)

10. *Treatment of cystitis:* Rest in bed; the imbibition of plenty of milk and water, and the avoidance of all highly seasoned food; laxatives; diuretics; sitz-bath; irrigation of the bladder with an antiseptic solution; hot fomentation and vaginal douches are often helpful; sometimes intravesical medication is necessary.

SURGERY.

1. An *aneurysm* is a pulsating sac containing blood, and communicating with the lumen of an artery.

A *true aneurysm* is one in which the sac is composed of one or more of the coats of the artery.

A *false aneurysm* is one whose sac contains no arterial coat, but is formed of condensed perivascular tissue.

A *sacculated aneurysm* is one in which the dilatation is pouch-like; only a part of the circumference of the artery is involved.

*Aneurysm may be confounded with:* Tumors, cysts, and abscesses lying over the course of an artery.

In the *abscess*, the pulsation is not expansile, there is no bruit, the swelling may sometimes be lifted away from the artery, and the size and pulsation of the swelling are not affected by pressure on the artery. In the *aneurysm*, the opposite conditions prevail.

2. The *inflammatory diseases of bone* are: Ostitis, periostitis, osteomyelitis, and osteoperiostitis.

*Treatment of acute osteomyelitis* consists in relieving the constitutional symptoms and preventing the bone from necrosing. An incision down to the bone is made; if pus is beneath the periosteum, the latter is also incised; a piece of bone is removed by chisel or trephine, pus is removed, the endosteum is hurt as little as possible, the wound is irrigated with hot bichloride solution and packed with gauze; the soft parts are closed and the wound well drained. In case this fails, amputation may be necessary.

*Dislocation* is a displacement (partial or complete) of the articular end of a bone.

*Fracture* is a sudden forcible solution of the continuity of a bone.

| FRACTURE. | DISLOCATION. |
|---|---|
| 1. Crepitus may be present. | 1. Crepitus never present. |
| 2. Preternatural mobility. | 2. Rigidity rather than mobility. |
| 3. Easily reduced—but | 3. Difficult to reduce—but |
| 4. Deformity more liable to recur after reduction. | 4. Deformity less liable to recur after reduction. |
| 5. The head of the bone is in its proper place. | 5. The head of the bone is not in its proper place. |
| 6. The socket containing the head of the bone is not empty. | 6. The socket which should contain the head of the bone is empty. |
| 7. When rotated the bone does not move as one piece. | 7. When rotated the bone moves as one piece. |

*Two essential principles in treatment of fractures:* (1) Reduce the fracture; (2) retain it in position.

3. *Symptoms of fracture of the spinal vertebræ, with pressure:* "The local signs are often but little marked. There may be pain at the seat of injury or some inequality in the spinous processes; but as often as not these are absent. The general signs depend upon the condition of the cord, and none will be present when it has escaped injury. But when it is compressed or crushed there will be paralysis of the parts below, more or less complete, according to the extent of the lesion. Taking as an example a case of fracture in the lower cervical or upper dorsal region—the most common situation—with severe compression or crushing of the cord, there will be paralysis of both motion and sensation of the whole of the parts below the seat of injury (paraplegia), and perhaps a zone of hyperesthesia immediately above the injured part due to

irritation of the nerve-roots that issue just above the damaged part of the cord. The intercostal muscles being paralyzed, respiration can only be carried on by the diaphragm, this muscle receiving its nerve-supply through the phrenics which are given off above the seat of injury. Hence, while the chest is motionless, the abdomen rises and falls during respiration. The bladder and rectum and their respective sphincters share in the paralysis, so that there is at first retention of urine and feces, followed by passive overflow of urine as the bladder becomes distended and will hold no more, and by involuntary passage of feces. Priapism, or involuntary erection of the penis, is frequently present, or is induced by the use of the catheter. The temperature varies; sometimes it may be lower than normal, but often it is considerably raised, even reaching as high as 107° F. shortly before death. Consciousness, unless any head injury has been received at the same time, is not affected. The reflexes in the lower limbs are usually at first in abeyance, but may return if the patient does not succumb to the shock of the injury. If the deep reflexes remain quite lost the probabilities are that the conducting power of the cord has been completely destroyed. If they return it is a sign that some power of conductivity is left in certain portions of the cord at the seat of injury. Death occurs, as a rule, within from twenty-four hours to a few days from bronchial trouble; but the patient, if the fracture is in the upper dorsal region, may linger for two or three weeks. The secondary troubles which are then generally met with are bedsores and chronic cystitis." (Spencer and Gask's *Surgery.*)

"*A total transverse lesion* gives rise to: (1) Complete flaccid paralysis of all the muscles innervated by the cord below the segmental level of the lesion (this is in contrast to subtotal transverse lesions in which spastic paralysis occurs); (2) complete anesthesia below the segmental level of the lesion; (3) absent kneejerks, and other deep reflexes below the segmental level of the lesion (occasionally certain of the cutaneous reflexes, such as the plantar reflex—dorsal flexion of the toe, the Babinski sign—may be preserved); (4) atrophy of the paralyzed muscles; (5) partial or complete reactions of degeneration; and (6) loss of control over the vesical and rectal sphincters."

"*Lesions limited to one lateral half of the spinal cord* give rise to the following characteristic symptom-complex, named after Brown-Séquard: (1) On the side of the lesion: (a) motor paralysis on a level with and below the lesion—flaccid paralysis and atrophy, with the reactions of degeneration of the muscles innervated by the segment of cord destroyed, and spastic paralysis of the muscles innervated by lower motor neurons below the destroyed segment of the cord (due to degeneration of the pyramidal tract—upper motor neuron); (b) a segmental zone of complete anesthesia (protopathic, epicritic, and deep sensibility) corresponding to the spinal-cord segment destroyed; and (c) below the level of the lesion—normal or increased protopathic and epicritic sensibility, but usually lessening of the deep sensibility (muscle sense). (2) On the side opposite the lesion: (a) lessened protopathic (pain) and epicritic (tactile and temperature) sensibility; and (b) normal deep sensibility, muscular power, and reflexes." (Kelly's *Practice of Medicine.*)

"Removal of the laminæ and spinous processes of one or more of the vertebræ is done to relieve pressure on the cord from depressed bone, inflammatory material, callus, cicatrices, or tumors. It is useless in cases where the spinal cord has been completely divided or one segment is totally disintegrated. The presence of the deep reflexes, or their return after a little time, indicates that the lesion is not a complete one, and so may justify operation. Other cases suitable for operation are: (1) Injuries which involve the cauda equina; (2) depressed fracture of a neural arch; (3) bilateral dislocation of the cervical spine; (4) paraplegia arising after an interval from the pressure of blood or inflammatory exudation, cicatrices, or callus." (*Aids to Surgery.*)

4. The *scrotal hernia* will give an impulse on coughing, is not translucent, may be reducible, may be resonant, is not fluctuating. The *hydrocele* gives no impulse on coughing, is translucent, is not reducible, is not resonant, and is fluctuating.

*Hernia* is the protrusion of an internal viscus through an abnormal opening in the parietes.

*Strangulated hernia* may be treated by taxis or by operation.

For *inguinal hernia,* many operations are practised, but Bassini's is the most useful. An incision 2½ inches long is made over the inguinal canal, exposing the structures of the cord and the external oblique. The external oblique fibers are split from the apex of the external ring to expose the canal. The sac is found, opened, emptied of its contents, and isolated from the structures of the cord up to the internal ring. If the hernia is irreducible, the intestine is freed and returned to the abdomen, omentum being ligatured and removed. The neck of the sac is then transfixed and tied with silk, and the fundus removed. The stump returns to the abdomen, three or four stitches are then passed through the conjoined tendon and arched fibers of the internal oblique and transversalis muscles above, and the deep part of Poupart's ligament below. These are tied behind the cord. The external oblique is then sutured in front of the cord, leaving just sufficient opening for it to pass through without pressure. The skin is then closed by a continuous stitch. The patient should be kept in bed for three weeks, and should not exert himself for at least six weeks. If the wound has suppurated, or if the case is one in which the abdominal muscles are weak, it is advisable that a light truss should be worn afterwards for six months." (From *Aids to Surgery.*)

5. A *tumor* is a pathological new growth which tends to persist independently of the tissues in which it is found, and which serves no physiological purpose.

An *adenoma* is a tumor formed of gland tissue.

An *angioma* is a tumor formed of dilated vessels (either blood-vessels or lymphatic vessels).

"*Dermoid cysts* of the simpler kind have a wall composed of the structures forming the skin and its appendages, viz., stratified squamous epithelium, dermis, hair-follicles with hair, sebaceous glands actively secreting their contents; also subcutaneous fat and sweat-glands. They are commonly met with: (*a*) in the skin of the scalp, or (*b*) attached to the periosteum and quite separate from the skin, above the outer angle of the orbit, (*c*) in the middle line of the floor of the mouth, below the tongue, (*d*) in the lines of the embryonic fissures in the neck, (*e*) in connection with the thymus, (*f*) in connection with the ovary in the female, and (*g*) between the bladder and rectum in the male. The more complicated dermoid cysts which merge into the teratomata are especially those connected with the ovary, with the base of the skull around the hypophysis protruding into the nasopharynx as hairy polypi, and with the spinal column."—(Spencer and Gask's *Surgery.*)

*Indications for removal of mammary gland:* Enormous hypertrophy, Paget's disease of the nipple, epithelioma of the nipple, carcinoma, sarcoma, cystic adenoma, diffuse tubercular or septic disease if breast is riddled with sinuses.

6. "When a wound is inflicted while dissecting, wash it under a strong stream of water, squeeze, and suck it to make the blood run, lay it open if it be a puncture, paint it with pure carbolic acid, and dress it with iodoform and hot antiseptic fomentations. Trouble, of course, may follow; often it is only local and a small abscess forms. It should be treated by hot antiseptic fomentations and early incision. Occasionally lymphangitis arises, adjacent glands inflame, and constitutional symptoms arise. It is rarely that true septicemia or pyemia arises unless the wound was inflicted while making a post-mortem upon a person dead of septicemia or while operating on a septic focus. If glands enlarge and soften it may be necessary to remove them surgically."—(De Costa's *Surgery.*)

In the early stage of an abscess, when suppuration is doubtful, treat as if it were an acute inflammation. When pus is evidently present, incise freely, open secondary loculi, swab out the pus, do not curette, irrigate with antiseptics and drain.

*Symptoms of psoas abscess:* "There may be none, old unsuspected psoas abscess being often found at the autopsy. Early symptoms depend upon irrigation of the lumbar nerve roots—namely, sciatica, cruralgia, or neuralgia of the anterior crural. Aching across the hip and back and the base of the sacrum; cramp, and at times paralysis. Inability to extend the thigh. Children merely complain of a pain down the thigh, and always carry it flexed. Deep pressure in the abdomen, along the semilunar line, reveals a vertical, sausage-shaped, tender, fluctuating, elastic tumor (mistaken for loaded bowels, but which does not roll from under the fingers). It may or may not reach Poupart's ligament and may be accompanied by a tumor of similar character in the iliac fossa. The abscess may run its course without any subjective symptoms, the extra abdominal tumor first attracting attention. When extra abdominal the usual physical signs show it to be abscess; and the impulse on coughing that it has intraabdominal connection; combined pressure above Poupart's ligament and over the tumor in, e. g. the thigh, reveals fluctuation. Psoas abscess is most likely to be overlooked when symptoms of spinal or sacroiliac disease are not coexistent."—(Heath's *Dictionary of Surgery.*)

*Psoas abscess may be confused with:* Loaded intestine, hernia, bubo, and abscess near or connected with the vermiform appendix.

7. *Epispadias* is a congenital malformation in which the urethra opens on the dorsum of the penis.

*Hypospadias* is a congenital malformation in which the urethra opens on the under surface of the penis.

*Phimosis* is the condition of the prepuce when it cannot be retracted over the glans penis.

*Paraphimosis* is the condition of the prepuce when it has been retracted behind the glans penis and cannot be replaced.

*Causes of phimosis:* A long narrow prepuce, a small preputial orifice, adhesions of the prepuce to the glans penis, balanitis, and herpes preputialis.

*Treatment of phimosis* is circumcision. In the operation of circumcision the prepuce is drawn well forward, and clipped with a pair of polypus forceps in front of the glans; the projecting end cut off; the cutaneous sheath allowed to retract, and the mucous membrane slit up along the dorsum as far as its attachment. Each half is then cut away, following the line of the corona, and leaving the frenum and just enough to hold a few sutures. If catgut is used, and the wound dried and covered with iodoform, the dressing may remain on until the skin has united.—(*Pocket Cyclopedia.*)

8. Fistula in Ano.—*Classification:* There are four varieties: (1) The *complete,* which opens into the rectum internally and on the perineum externally; (2) the *external incomplete* or *blind external,* which opens on the perineum but not into the rectum; (3) the *internal incomplete* or *blind internal,* which opens into the rectum but not on the perineum; (4) the *horseshoe* fistula, which extends around the rectum and opens on each side. The internal opening is generally between the two sphincters, but may be above the internal sphincter and below the external sphincter. There may be several pockets or side tracts extending in different directions.

*Treatment:* This consists in "the conversion of the fistula into an open wound so that it may heal from the bottom. A grooved director is passed through the fistula into the rectum, and the overlying tissues severed with a bistoury. The sphincter should never be cut more than once, because of the danger of incontinence. All branching sinuses likewise should be opened, and all fibrous tissue, with undermined skin, cut away with scissors. The bleeding is then checked, and the wound packed with iodoform gauze. If the fistula is lined with mucous membrane it must be completely excised. A blind external fistula may be excised and the wound sutured. A blind internal fistula may be converted into a complete one and treated as above. The bowels are confined for the first three or four days and the wound dressed after each defecation, being irrigated with creolin and repacked with iodoform gauze."—(Stewart's *Surgery.*)

*Operation for hemorrhoids:* Clamp and cautery. *Radical treatment* is advisable when there is much pain and bleeding. It must be ascertained first that the piles are not due to disease elsewhere, as cirrhosis or stricture, or to pregnancy. The bowels are emptied and the patient is placed in the lithotomy position. The sphincter is then dilated with two thumbs, to expose the piles, which are caught up with ring forceps. A clamp is applied to the piles in turn, and they are removed by the cautery. The bowels are kept confined for five or six days, when castor oil is given. Very little pain and no bleeding follow this operation. Removal can be done by snipping the mucous membrane around the pile and ligaturing its base. Crushing is also done.—(*Aids to Surgery.*)

*Shock* is the name given to a sudden and general depression of the vital powers due to some strong stimulation (such as injury or emotion) acting on the vital centers in the medulla, and producing vasomotor paralysis.

*Treatment of shock:* Place the patient in the recumbent position, with the head low, apply warmth to the body, administer a stimulant, and give a hot saline infusion; morphine, hypodermically, may be necessary for the relief of pain.

*General anesthesia* may be produced by: Nitrous oxide, ether, chloroform, ethyl chloride, by numerous modifications of the above agents, and by various sequences and mixtures.

*Nitrous oxide* is contraindicated in long operations, where absolute muscular relaxation is needed, in vascular degeneration, and advanced heart disease.

The following contraindications for ether and chloroform are from Hare's "Practical Therapeutics": "*Ether* should not be used by inhalation in bronchitis or acute nephritis, because of its irritant properties; in peritonitis or gastritis, because it is apt to induce vomiting; in aneurysm or in the presence of marked vascular atheroma, because it may rupture a blood-vessel by raising arterial pressure; nor in diabetes, lest it produce diabetic coma; and if anemia is present and an examination of the blood shows that the hemoglobin is below 50 per cent., the use of the drug should be avoided if possible.

"*Chloroform* is not to be used in cases of fatty heart or dilatation of the heart, in those with a known idiosyncrasy, nor in the so-called lymphatic persons with overgrowth of lymphoid tissues, as, for example, adenoids. In the latter case it is particularly apt to cause sudden death. In valvular disease of the heart chloroform may be used with caution, although ether is preferable. Given a case of valvular disease that must be subjected to operation, the chances are bettered with an anesthetic than without it, as the pain and mental shock are worse for the heart than is the anesthetic."

10. The following table (from Eisendrath's "Surgical Diagnosis") gives the diagnosis:

| COMA FROM INTRACRANIAL INJURY. | APOPLECTIC COMA. | UREMIC COMA. | ALCOHOLIC COMA. | OPIUM POISONING. |
|---|---|---|---|---|
| Deep coma. Evidence of fracture of vertex or base. | Deep coma; sudden onset. If any injury, only a scalp wound. | Deep coma. Slow onset unless convulsions have preceded. | Can be aroused by supraorbital pressure unless very profound | Can be aroused unless very deep. |
| Pupil dilated on side of lesion. Choked disc. | Pupils unequal or dilated. Contracted in pons hemorrhage. | Albuminuric retinitis. | Pupils normal or somewhat dilated. | Pupils contracted to pinpoint size. |
| Pulse very slow. | Pulse full and slow. | Pulse rapid. | Pulse rapid. | Pulse rapid. |
| Respiration slow and stertorous. | Respiration slow and irregular. | Respiration frequent and irregular. | Regular respiration. | Respiration very slow—may be 6 to 8 per minute. |
| Temperature higher—101°. | Temperature higher on paralyzed side. | | May be low or normal. | |
| Urine normal or contains albumin. | Urine contains trace of albumin. | Urine shows albumin, casts. | Normal. | Normal. |
| Hemiplegia on opposite side to that of injury. | Hemiplegia with convulsions on one side. | | | |

*Septicemia* is an acute general infection arising from the presence of pyogenic organisms in the blood. The *Streptococcus pyogenes* is the usual organism. Infection occurs through a prick, scratch, or abrasion, or through an operation wound. *Symptoms:* A rigor is often the earliest symptoms, followed by a rise of temperature to 104° F., which remains constant. The pulse is increasingly rapid and becomes weak. Diarrhea comes on later, while the urine contains albumin. *Diagnosis:* From sapremia, or traumatic fever, it is known by the fact that opening up and draining the wound makes no difference to the condition, whereas in sapremia the patient gets rapidly better. From pyemia, by the fact that there are neither repeated rigors nor secondary abscesses.

*Pyemia* is an infective disease characterized by rigors, marked intermittent fever, and the development of secondary abscesses. The organisms present are either staphylococci or streptococci. *Symptoms:* Severe rigors repeated at intervals of one to two days. The temperature rises to 103° or 104° F. and remains so for about an hour, then falls rapidly, accompanied by profuse sweating. The patient often becomes jaundiced, and signs of abscesses in the lungs, joints, etc., become apparent. The pulse becomes rapid and weak, the appetite is bad, and delirium follows. Infective endocarditis may occur. The secondary abscesses appear at the end of the first week, and form very rapidly. *Diagnosis:* No mistake can be made when a focus of infection is apparent. If such cannot be found it may be mistaken for malaria.—(From *Aids to Surgery.*)

## Therapeutic Hints.

Treatment of Psoriasis.—Haldin Davis states that the drugs which, taken internally, are of benefit in this disease, are arsenic, thyroid extract, and salicin. Of these, the oldest and most generally used is arsenic. It may be given in several different ways: (1) In the form of Fowler's solution, of which three to six drops are given three times a day after meals. It is conveniently prescribed with an alkaline bitter, as follows:

℞ Liq. potasii arsenitis, ♏ij-vj.
Sod. bicarb., grs. x.
Inf. gent. co., q. s. ad ℥ j.

The dose of arsenic is gradually increased by one drop every third or fourth day up to as much as 20 drops. (2) Arsenic may be administered in the form recommended by Kaposi, in the so-called Asiatic pill, the formula of which is as follows:

℞ Arseni trioxidi, gr. 1/20 to 1/10.
Piper. nigri, gr. ¾.
Acaciæ, q. s.

Kaposi used to give a course beginning with three pills a day and gradually increasing to eight or ten. He would push the drug until four to six hundred pills had been taken. It is doubtful whether it is advisable to push arsenic to such a point; as a rule, if arsenic is of any benefit at all, small doses are sufficient. Sometimes good results are obtained from the use of thyroid extract, which, however, should be given cautiously. One grain, twice daily, is sufficient as an initial dose. Salicin is useful in the initial stages of psoriasis in limiting the hyperemia. Recently Sabouraud reports good results from the injection of enesol (a combination of arsenic and mercury with salicylic acid) in doses of ½ grain twice weekly.

The external treatment of psoriasis is more important than the internal. It is frequently effective unaided. The first essential of the treatment is the removal of all the scales, which should be done daily with the liberal use of soap and water, and warm baths containing sodium carbonate, two drams to each gallon of water. If the scales are hard and dense, they may be removed with the use of olive oil containing five grains of salicylic acid to every ounce. After the scales have been removed, one of the derivatives of tar should be applied in the form either of a lotion or of an ointment. A useful preparation is liquor picis carbonis, of the British Pharmacopœia. This contains prepared coal tar (picis carbonis), 1 part, in tincture of quillaria, 5 parts. It may be used in a solution in the strength of a dram to a pint. Such a lotion is useful in widespread eruptions. The following ointment is also useful:

℞ Liquor picis carbonis (B. P.), grs. viij.
Hydrarg. ammon., grs. x.
Petrolati, q. s. ad ℥ j.

Another tar preparation is anthrasol, which may be incorporated in an ointment as follows:

℞ Anthrasol, ℥ j.
Petrolati, q. s. ad ℥ j.

Oil of cade may be used in the strength of one dram to one ounce of petrolatum. Salicylic acid is useful for its power of reducing hyperkeratosis. The following is a good formula:

℞ Acidi salicylici, grs. xv.
Ichthyol, grs. xxx.
Petrolati, q. s. ad ℥ j.

The most powerful local remedy is chrysarobin, which should be used with caution. It should not be used near the eyes, for it may cause a severe conjunctivitis, nor on the scalp, for it stains the hair. It is best used with the patient in bed, or at all events, kept under constant observation. In the beginning it should be employed tentatively on one limb only. Chrysarobin may be combined with tar, as in Hutchinson's formula:

℞ Chrysarobin, grs. xxx.
Hydrarg. ammoniat., grs. x.
Liq. carbonis detergens, ♏xx.
Petrolati, q. s. ad ℥ j.

This should be rubbed in every morning vigorously and the part should be covered with a bandage. If well borne without excessive irritation, its use should be gradually extended over the whole of the affected area.

In the case of psoriasis of the scalp, the latter should be shampooed frequently with a spirit soap. Chrysarobin cannot be used on account of its staining properties. Tarry compounds should be applied, preferably in the form of a lotion, such as the following:

℞ Anthrasol, ℥ iv.
Tinct. quillajæ, ℥ ij.
Spir. vini, ad ℥ iv.

This may be applied by means of a stiff brush, for example, an ordinary tooth brush.—*Universal Medical Record.*

Treatment of Eczema in Young Infants.—According to P. Rudaux, A. Grosse and V. le Lorier, infantile eczema is almost invariably a manifestation of overfeeding. The treatment, therefore, is chiefly one of regulating the diet. For the local treatment the following salve is recommended by Sabouraud:

℞ Zinc oxide, 7 grams.
Vaseline,
Lanolin,
Sweet almond oil, of each, 10 grams.
—"Thérapeutique Obstétricale."

The Rationale of Squill as a Diuretic.—A. Pic and S. Bonnamour state that squill should be included among the direct diuretics, which have an elective action upon the elimination of urea by the renal cells. In cases of nitrogen retention, squill increases diuresis, but causes to a greater degree an increased elimination of urea.—*La Presse Médicale.*

Treatment of Herpes Gestationis.—P. Rudaux, A. Grosse, and V. le Lorier outline the following treatment of this form of gestational autotoxemia: (1) Rest in bed. (2) Absolute milk diet. (3) The use of laxatives daily, or of purgatives every three days with saline enemata on the intervening days. (4) A warm starch bath lasting one-half hour every day or every other day. (5) The use twice a day of the following lotion:

℞ Chloral hydrate, 10 grams.
Distilled water, 1000 c.c.

After this, the application to the itching parts of a powder, made up as follows:

℞ Salicylic acid, 1 gram.
Powdered starch,
Powdered talc, of each, 50 grams.
Zinc oxide, 10 grams.

If the itching is intolerable, it may be necessary to administer chloral hydrate internally. In case the stomach does not tolerate this drug, it should be given per rectum in doses as high as 2 grams, dissolved in boiled water or milk.—"Thérapeutique Obstétricale."

### THE WORK AND NEEDS OF THE ACADEMY OF MEDICINE.*

BY WILLIAM M. POLK, M.D.,

NEW YORK.

FELLOWS OF THE ACADEMY:

I beg to acknowledge my indebtedness for the great honor conferred upon me in making me your president for a second term. In order that you may recall what was done during the two years just closed, I will submit a statement briefly covering our activities in this period. In the field of pure science the most noteworthy contributions received by us came from Professor Loeb of the Rockefeller Institute and Professor Rubner of the University of Berlin. The latter presented here for the first time certain observations in associated concrete form relating to the "Life of a Cell," which he himself had made but recently. The value of the contribution and the interest which it aroused was fully attested by the number of distinguished biologists present at the meeting and the close attention given to what, of necessity, was a highly technical presentation of a difficult subject. The genius of the investigator was in evidence in the clear and simple manner of this presentation of his labors.

The year before (1911) we had heard an equally interesting and instructive discourse on "The Rôle of Salts in the Preservation of Life" by Professor Loeb. His accomplishments in this particular field had already won for him a first place in the ranks of those seeking for the beginnings of cell life, so that having had placed before us by Professor Loeb himself a masterly presentation of his discoveries in this fascinating field, we may count ourselves as having in both instances fulfilled to the letter the purposes of the Carpenter Lectureship, under which they came. Bearing upon this subject of cell life and coming between the expositions of Professor Loeb and Professor Rubner, we had demonstrations from Dr. Carrel upon the preservation and extension of cell life in so-called dead tissues, through the aid of cold storage. Taking in connection with this latter work, certain accomplished facts relating to the transplantation of tissue and even organs, and viewing it all in the light shed upon cell life and proliferation by the papers of Professors Loeb and Rubner, ample inspiration was furnished us for thought and effort in the highest realms of biology. Pure physiology on the one hand, and its direct connections with the every-day problems of surgery on the other were much more than suggested—they were pointed out.

In the presentation of his work bearing upon the "Pathogenesis of Goiter in the Lower Animals," the Chief of State Laboratory for Cancer Research at Buffalo added to our fund of information concerning the still mystifying thyroid gland. One of the programs presented by the Section on Otology and another by that on Neurology and Psychology were papers relating to the physiology of the semicircular canals and to the results of stimulation and extirpation of these canals. If these papers could have been brought closer together in a joint meeting, for instance, it would have been advantageous. This suggests a defect in the correlation of your sections, against which some provision must be made. Another most interesting question discussed before us was some of the concepts of the Freud School of Psychopathology. Ably presented by our guest, Professor Putnam of the Harvard School, it was earnestly and with like ability reviewed in discussion by some of our members. The frank treatment given the subject on that occasion was an admirable illustration of the type of presentation and analysis questions brought here are entitled to and which with few exceptions they receive. I am happy to report that cheap subjects cheaply presented are rare at your meetings.

In the domain of "applied knowledge" we have also been fortunte. For instance, under the head of causation and nature of disease, we class the papers on developmental affections, such as deaf mutism and those on embryonal vices as the basis of certain gynecological diseases. Under the same head the paper on autointoxication as a cause of eye diseases; also the papers on recent advances in our knowledge of cardiovascular diseases, and reports of experimental work upon the problems of pneumonia and of poliomyelitis; observations upon new diseases, and new aspects of diseases already differentiated and registered. New remedial agents, such as salvarsan; and new routes for applying treatment, such as is implied in duodenal alimentation; and the reason for and the need for more extended use of psychoanalysis. And when to this list of subjects, all presented in a manner in keeping with the repute of the distinguished speakers, we add those belonging to general surgery and its divisions, including therewith the demonstrations of increased efficiency of radiology in the domain of intestinal surgery, I am sure we find that the primary purpose of the New York Academy of Medicine has been again lifted up and advanced.

It is necessary to bear all this in mind, because in some respects during the past two years this academy, perhaps oftener than heretofore, has stretched out its hand to influence conditions relating more to the welfare of the community along general and sociological lines, but which bore upon the causation or otherwise of one or more particular diseases with which it might be concerned. It has done this through the activities of its committee on "Hospitals, Budget, and Public Health."

*Address of the President delivered January 2, 1913.

The committee has been actively represented by the chairman and members of the committee on the following occasions:

At the hearings before the Legislative Committee on the Charter.

At the meeting on Outside Cooperation with Public Schools, arranged by the President of the Board of Aldermen.

At the conferences on various phases of administrative health work with the commissioner and the officials of the Health Department.

Twice at the hearings before the Committee on Elementary Education of the Board of Education with reference to the need of physicians for general school hygiene and the examination of mentally defectives.

At the hearings before the Board of Estimate and Apportionment in 1911 and 1912 on the budgets of the Health Department, the Department of Bellevue and Allied Hospitals, the Department of Charities, and the Department of Education.

At the conference on nursing.

At two conferences on the subject of bettering the health conditions in the public schools.

At the conference on ventilation arranged by the Association of Heating and Ventilating Engineers, the New York Association for Labor Legislation, and the Special Committee on Ventilation of the Department of Education.

At the hearing before the Mayor on the Aldermanic Cuts in the Budget for 1913.

At the hearing on the bills to be presented at the next meeting of the Legislature by the Factory Investigation Commission.

At the Fifteenth International Congress of Hygiene and Demography.

*Publications.*

The report on the Need of a Contagious Disease Hospital in the Bronx was published by the Committee at its own expense and submitted to the members of the Board of Estimate and Apportionment, various civic bodies, and the newspapers.

The report upon the Health Conditions in the Public Schools of New York City was published in the MEDICAL RECORD of August 30, 1912.

The report on Vital Statistics and the Health Reports of New York City was published in the MEDICAL RECORD, November 23, 1912.

The report on the need of transferring the Quarantine at the Port of New York to Federal control is to be published in the *Journal of the American Medical Association*.

This committee has also been cooperating with the following agencies:

The Babies' Welfare Association.

The Public Education Association Committee on the Hygiene of School Children.

The Special Advisory Committee of the Department of Health on the Administrative Control of Typhoid Fever.

The Special Advisory Committee of the Department of Health on Milk Inspection.

The Joint Committee on Occupational Diseases appointed by the New York Association for Labor Legislation.

The Board of Estimate and Apportionment Special Committee on Hospital Inquiry.

Requests for cooperation were received from the Laity League of the New York Federation of Churches with regard to Sex Education and from the Conference of Social Workers relating to the matter of employment of the physically handicapped.

The Board of Inebriety.

The Municipal Civil Service Commission.

Russell Sage Foundation in the matter of autopsies.

The actual inspections covered in this work, such as gathering of evidence, examinations of reports, interviews with heads of departments and sifting of evidence, etc., involved a great deal of labor on the part of the members of this committee, all of which has been rendered in that spirit of unselfish devotion to the higher purposes of our profession, which this self-seeking age was beginning to view as an aspiration on our part too seldom realized. This committee has been most fortunate in its executive secretary, Mr. Lewinski-Corwin, who so ably fulfilling the requirements of his office has enabled the committee to present its conclusions in such form as to carry conviction in many instances, and always to command attentive and respectful hearings. In deciding to continue this committee your council has acted for the best interests of your association. It is necessary to remember, however, that this work is such that the funds of your academy would be unable to meet the expense involved. This is done by one of our most generous and open-hearted citizens, to whom we are especially indebted for enabling us to do work of this nature.

It is becoming more and more evident, because of the position medical expert testimony has been made to assume in our courts of law that our profession has been put in a position before the public far from that intended for it, and some distance from that best for seekers after truth, the whole truth, and nothing but the truth. No doubt the rights of the individual and "due process of law" work together to force the expert witness from his proper position as an impartial expounder of medical, surgical, or chemical facts into that of associated council or even advocate for the side which he serves in the controversy. A most distinguished jurist of the State, one who has been active in efforts to reform court procedure in this matter, gave us a year ago the benefit of his presence and an address on the subject.

An outcome of this meeting was a committee of your members who, after study, made recommendations which were adopted by you. The purport of these resolutions was to the effect that a medical expert should not act in the rôle of counsel as well as witness in the same case. Of course, such a restriction cannot be enforced by any action which this or any other medical organization might take, this can be done only through legislation. Such being the case the only remedy open to the profession of medicine is the acknowledgment that under our system such a thing as an uncolored, unbiased statement of facts in any case of legal controversy is not to be expected from any medical expert who holds the dual position of witness and counsel; because he will consciously or unconsciously so far merge the witness into the advocate as to lose touch with the accepted facts of medicine and surgery which bear against his own side, in the vividness with which he recalls and presents such as favor it. In other words, while we have many very able medical expert witnesses, who as paid retained witnesses, have a most important and desirable place in our Courts of Justice, and who sho ld

be paid as they now are by the parties to the suit who employ them, we have few, very few, medical experts in the sense of one who is so placed that he can give, unbiased, uncolored interpretations of the medical and surgical problems submitted before the law courts, regardless of the two sides of the controversy. The position which the paid witness assumes becomes fundamentally a matter between himself and his employers—and seeing that it is difficult for such a one to maintain our professional standards for the expert, in proportion to his activities in upholding the requirements of his client, would it not be better pending legislative relief, to rank such witnesses, not as "medical experts" but as "medico legal experts." The first to be an employee of the court, the latter an employee of parties to the controversy. So far we have only the latter, "medico legal experts."

Another sore spot with our profession is the pernicious practice known as "secret fee splitting." We have met this for ourselves in our own way, by the series of resolutions passed by you last year. But after all, is this enough? It should be, so far as your own ranks are concerned. But one can imagine cases in which even for your own protection your own measures might prove inadequate. It is interesting to learn that something is being formulated in this State which may put us in touch with machinery for dealing with delinquents, which will resemble similar machinery in the profession of law.

The legal profession protects itself through the powers of the Appellate Division of the Supreme Court, before which an offender against the ethics of that profession can be brought and disciplined, even to the extent of expulsion from the courts. The Board of Regents in this State is the only body which controls the licensing of practitioners of medicine, therefore it is the only body competent to deal with offenders whom our powers fail to reach. It can do for us what the Appellate Division does for the Law.

The picture of two or more practitioners of medicine counseling together in secret, concerning the fee their common patient is to be called upon to pay, not for all the service rendered by the combination in the given case, but for that to be rendered by the consultant plus the amount added to his fee to meet the commission granted and expected by the so-called family doctor for bringing the patient to this consultant, is not pleasing. It is easy to see how any consultant who adopts this course can soon secure a following of "family doctors" who, caught in the contagion of this debasement, join in the common debauchery. We have here nothing less than a conspiracy against the one person the ethics of our calling command us to protect. And the way of protection is so easy—simply admit the patient or his representative to the conference. There then can be no breach of confidence, no conspiracy, therefore nothing calling for reprehension. Is not "secret fee splitting" so serious a threat to our professional integrity, so detrimental to the standing of our profession, that this body would be evading its duty were it not to ask the Board of Regents to seek such legislation as would permit it to withdraw the license to practise from any one proved guilty of the offense? I think it is, and I am sure we would shirk our duty did we not seek such legislation.

Whether we would or not this academy holds a position in this city which makes it a vital necessity not only that it should hold and maintain high ideals within itself, but should do all in its power toward this attainment throughout the entire profession. Through our committee dealing with public questions, and whose activities have already been placed before you, we aim to gain public confidence by showing that we are striving for the good of the whole along the broadest paths which have been opened up by the science and art of medicine. The hands which we stretch out to them must be free from the suspicion of questionable gain, especially at their expense. In all our relations with them we must play fair as well as talk fair.

At the present time we are soliciting aid from the public toward a new building for this academy. This movement was taken up some three years ago, the initial effort being confined to seeking aid from our own members and such other members of the profession as we could interest in the endeavor. The treasurer has already submitted to you a statement upon this matter, but it is in place to summarize this statement here. Subscribed to date chiefly by our members $123,275; paid to date, December 23, 1912, $64,800, which with interest to date, makes $67,800.

This with our other assets makes one feel that within the year we may be able to begin definite work toward the fulfillment of our demands for a new building. You realize that the most insistent demand comes from your library, the force of which you will readily appreciate when I read you this extract from the report of your library committee:

"We offer for your consideration a statement of the growth of the library and its activities based on a detailed study of the records of the past twenty years.

1892-1912: Books acquired have increased 250 per cent.
Pamphlets acquired have increased 440 per cent.—35,600 to 140,263.
Readers have increased 165 per cent.—7,752 to 20,548 per annum.

1902-1912: Circulation of books and periodicals. Has increased 168 per cent.—2,736 to 7,353 per annum.

1892-1912: Salaries have increased 116 per cent.—$5,564 to $12,062 per annum.
Library expenses have increased 57 per cent.—$2,829 to $4,459 per annum.

As will be seen the library has grown in all its departments at a rate which is beyond the estimates, and as a fact more rapidly than any other medical library in the country. It is a matter of satisfaction to see that this has been accomplished, and that the efficiency of the library has been maintained, at a proportionate cost decidedly less than in other libraries."

The combination which the Academy of Medicine presents is this: The largest purely medical library in the country, one administered in the best manner so as to meet the demands not only of our own members, but of the profession at large and of the public and which is united with activities which cover every phase and department of medicine, most of which it controls and all of which it houses. All this requires better accommodation than we now have. We must provide it as soon as we possibly can.

# A FURTHER CONTRIBUTION TO THE ACTION OF LACTIC ACID BACILLI ON THE PERCENTAGE OF GLUCOSE IN THE URINE IN DIABETICS.

By PHILIP HOROWITZ, M.D.,

NEW YORK.

In my previous report* of the cases treated with a culture of *Bacillus bulgaricus,* I mentioned three cases, the first in which I had tried the culture, with the result that the first two appeared to be entirely rid of the glucose from the urine, and the third was still showing traces. I have kept in touch with the cases and beg to report further that in case 1 the patient shows no glucose although he has been without treatment for eighteen months. During this time he has lived on a normal unrestricted diet, eating all the carbohydrates he wanted, and using sugar for sweetening his tea and coffee and other articles of diet. The second patient has now been without treatment for sixteen months, has also been living on a normal unrestricted diet and likewise shows an absence of glucose. The third patient has been practically without treatment since November, 1911, except that he would occasionally take one dose of the culture. He has been living on an unrestricted diet, eating everything and drinking his beer daily. He has put on eighteen pounds in weight, does not have to pass his water often, going nine hours on a stretch, the time he is on the car. His urine examination on October 15, 1912, shows a specific gravity of 1,017, traces of albumin and indican, and 1 per cent. of glucose.

The following cases again show the same results that I have obtained with the first three cases reported.

Case IV.—H. A. V., age 43, civil engineer, native of the U. S. Family history is negative to rheumatism, gout, diabetes, etc. His father and mother are both living and well. He was never seriously ill. Six years ago he was in a railroad accident and had his back badly strained. The present history dates back to this accident, as far as he can remember. While he was convalescing from this he began to drink excessively and have frequent micturition. He lost flesh and his general health became impaired. On examination he was found to pass a considerable amount of sugar. He was put on a restricted diet which was kept up for four years. If he happened to be a little careless with his diet his sugar reappeared in large amounts. Today, July 23, 1912, his diet is free from cereals and sugar. The examination of his urine shows a specific gravity of 1,020, marked traces of indican, pronounced traces of glucose, and no acetone or diacetic acid.

Treatment.—The patient was put on a culture of the bulgarian bacillus, 4 c.c. t.i.d. before meals, diluted in a little water. This culture contained about 165,000,000 bacilli to the cubic centimeter. He was also given some purgative to get his bowels in shape and to stimulate the liver somewhat. His diet was fairly liberal. He was allowed cereals, green vegetables, animal broths, broiled meats, fermented milk, but no fruits.

August 2, 1912.—Patient feels very well. He ate four oranges yesterday to see if there would be any glucose in the urine. The examination of the urine shows nothing abnormal. The specific gravity is 1,017, no indican, glucose, acetone, or diacetic acid. The same treatment was continued.

August 13.—Feels fine, has had no headache since he began treatment, whereas previously he used to get headaches quite often. The urine examination shows a specific gravity of 1,020, and again no sugar, indican, acetone, or diacetic acid. The same treatment, and fruits permitted.

September 3.—Is perfectly well. He passed 40 ounces of urine in the last twenty-four hours. The specific gravity is 1,020, and no glucose indican, acetone, or diacetic acid found.

October 29.—Patient feels and looks very well. He passed a little over two pints of urine in the last twenty-four hours. The examination of the urine shows a specific gravity of 1,028, which is probably due to the small amount voided, and no sugar, indican, acetone, or diacetic acid. He has been practically without treatment since September 3.

Case V.—S. S. M., age 41, Baltimore, Md., native of Russia. Family history is negative to diabetes, rheumatism, gout, cancer, etc. Father, aged 70, and mother, aged 72, are living and well. One sister is also living and well. He had the ordinary diseases of childhood, otherwise has always been perfectly well. About three months ago began to suspect that he had "kidney" trouble because he began to pass a considerable quantity of water, and on a chemical examination of the urine sugar was found. He drinks a considerable amount of water, and passes as much as sixteen pints of urine in twenty-four hours. His appetite is exceptionally good, bowels regular, and does not complain of any headaches. He claims that he has lost fifteen pounds. Before he became ill he weighed 170 pounds and now only 155. The examination of the urine shows a specific gravity of 1,012, glucose 0.5 per cent. urea, 0.7 per cent, and a few calcium oxalate crystals. There is no acetone, diacetic acid, or indican.

Treatment.—He was put on 4 c.c. of a culture of *B. bulgaricus,* four times a day, one dose before each meal and on retiring. The diet consisted of cereals, green vegetables, broiled meats and chicken, chicken and mutton broths, tea and coffee unsweetened, fermented and soured milk, orange, apple, and grape fruit.

September 11.—He feels very much better. He does not pass as much water, and he does not have to get up at night. The bowels are regular. The examination of the urine shows a specific gravity of 1,018, no sugar or acetone, a small amount of indican. The urea has increased to 1.1 per cent. as against 0.7 per cent. He passed only forty-eight ounces in twenty-four hours. The same treatment was continued.

September 22.—Feels better, but is somewhat nervous. He is afraid the conditions will come back; he passes a little more urine than before. The examination shows the specific gravity to be 1,014, no indican, glucose, or acetone. The urea is low, only 0.7 per cent. Treatment the same.

October 6.—He has been drinking a little more water than usual and therefore is passing a little more, otherwise feels perfectly well. He passed about three quarts of water. The examination of the urine shows a specific gravity of 1,016, no glucose, indican, or anything else abnormal. Urea is now up to 1.1 per cent. The same treatment continued.

October 11.—Patient feels very well. Is not pass-

*Medical Record, March 9, 1912.

ing much water but thinks that he is probably losing some weight. His appearance, however, is good. The urine examination shows a specific gravity of 1,018, a small amount of indican, no glucose, acetone, or diacetic acid, and the urea is somewhat greater in amount, being 1.4 per cent. Otherwise the report is normal. The suspension of the *B. bulgaricus* was continued, and he was given 1/30 of strychnine with 5 gr. each of the glycerophosphates of lime and soda. He was also allowed a baked potato, plain boiled (plain) fish, and sour sugar-free wine at his meals.

November 10.—Feels very well. Gained 10 pounds in weight. Passed only 2½ quarts of urine in the last twenty-four hours. His appetite is not so good as formerly, but he thinks it is normal now. He eats everything but sugar; has had ice cream, cake, etc. In two urine examinations, since he was here, there was no sugar. Urine examination shows sp. gr. 1,020, urea 1.4 per cent., no indican, sugar, acetone, or diacetic acid. He is going to take a little more of the suspension so as to be absolutely certain of no recurrence.

Case VI.—J. C. P., Jr., age 45, St. Louis, Mo., native of the U. S. The family history is negative to diabetes. Father, 72 years old, suffers occasionally from rheumatism; mother is 70 years old and perfectly well. He had all the diseases of childhood; typhoid fever and malaria twenty-five years ago; rheumatism eight or ten years ago.

The present history dates back to four years ago. At that time he began to pass a considerable amount of water, had excessive thirst and appetite, and lost about 70 pounds in eight months. He had his urine examined at that time and was told he had between 8 and 9 per cent. of sugar. Today, August 15, 1912, he is still from 55 to 60 pounds under weight. He is very tired and fagged out. He passed 224 ounces in twenty-four hours. That is equivalent to about 15¼ pints of water, or almost 2 gallons. The examination of the urine shows a specific gravity of 1,027, very decided indican, 5.6 per cent. glucose, and no acetone or diacetic acid.

The patient was put on 4 c.c. of a culture of lactic acid bacilli four times a day; 4 c.c. one-half hour before each meal, and a dose before retiring. He was given a teaspoonful of calcined magnesia in one-half glass of water, t.i.d. His diet consisted of soft boiled eggs, four slices of white toasted bread a day, oatmeal and rice in moderate amounts, buttermilk, broiled steaks, chops, and chicken, plain boiled beef and chicken, chicken and mutton broths, and the green vegetables, as spinach, green peas, string beans, celery, lettuce, and asparagus, without sauces.

August 22.—Patient feels very well today, only somewhat hungry. He passed only 5 pints of water, and drinks very much less than he used to. The urine examination shows the specific gravity 1,025, glucose, 2.6 per cent., marked indican, and no acetone or diacetic acid. The same treatment was continued.

September 5.—Patient feels very well. Passes very little water. The examination of the urine shows the specific gravity to be 1,028, indican still very marked, glucose down to 2.4 per cent., and no acetone or diacetic acid. The same treatment was ordered.

September 25.—The patient has been home in St. Louis for the past three weeks. He writes that he passed only 3¾ pints in the last twenty-four hours as against 15¼ when he first started treatment. He drinks hardly any water, as he has lost the marked thirst which he had at the beginning. The examination of the twenty-four-hour specimen shows the specific gravity 1,016, no sugar, albumin, acetone, or diacetic acid, numerous uric acid crystals, and very strangely large quantities of indican. The last is not the rule. I have found that the glucose disappears after the indican has diminished or disappeared. Here the indican is probably high because the patient is on a very large protein diet. The same diet and treatment was continued.

October 10.—Received letter and specimen today. He writes that he is very much worried, as he passed only forty ounces of urine in twenty-four hours, also that he has been without medicine for a few days. The specimen on examination shows a sp. gr. of 1,028, urea very high, 3.2 per cent., indican marked, traces of sugar, no acetone or diacetic acid. He again passes large quantities of uric acid crystals. The patient has been on a heavy meat diet, and without his medicine has gotten up some intestinal putrefaction, hence the above report. The same treatment and diet continued.

October 18.—Writes that he feels somewhat worried, as he has lost three pounds in weight and feels very cold. He is coming to New York City.

October 24.—The patient has come East. He feels very much better and looks very well. He has lost some weight, but that he attributes to very hard work. He passes now only three pints in twenty-four hours. His blood pressure is practically normal, only 110. The urine examination shows sp. gr. of 1,018, urea of 1.7 per cent., very much less indican than the last time; no sugar, acetone, or diacetic acid. The following diet was formulated for him: Breakfast.—Some broiled steak, lamb chops or chicken, toast and tea, and grape fruit. Lunch.—Some meat as above, with lettuce, string beans, spinach or asparagus (sometimes a chicken sandwich). Dinner.—Same as for lunch. Allowed also Apollinaris or Vichy, and was also told he may have a half of a moderate-sized baked potato. The culture was increased to four doses each day of 16 c.c. each and a capsule given containing strychnine gr. 1/30 and 5 grs. each of the glycerophosphates of lime and soda.

October 26.—Feels very well, and thinks he has gained some weight. He ate some grape fruit, however, which he thinks had been prepared with sugar. Also had nine slices of toasted bread, rice, and potato. The examination of the urine shows faint traces of sugar. Cut the bread to six slices and warned him about taking any food prepared with sugar.

October 27.—The examination of the urine today showed a sp. gr. of 1,012, small amount of indican, no sugar, acetone, or diacetic acid.

October 28.—Feels very well; gained about three pounds since he came East. Ate ham, rice, and potato. Passes much less urine. The sp. gr. is 1,020, small amount of indican, and no sugar. Same diet was permitted.

October 29.—After eating more potatoes, eight slices of toast, and a considerable amount of chicken, nothing showed in the urine to-day. He gained one pound since yesterday.

October 30.—He took advantage of his liberal diet and more potatoes were eaten than permitted. He feels very well and passes very little urine. The urine on examination, however, shows a trace of sugar with small amounts of indican. Potatoes were prohibited, but otherwise the same diet.

November 4.—Patient sent a specimen from the West. He claims he feels perfectly well. The examination of the urine shows a sp. gr. of 1,020, urea up to 1.9 per cent., some indican, but no sugar, acetone, or diacetic acid. The same treatment and diet were permitted.

November 10.—The examination of a specimen received by mail shows sp. gr. 1,022, urea 2.1 per cent., small amounts of indican, no sugar, acetone, or diacetic acid.

November 14.—Feels very well. Weighs about the same. Has been eating about eight slices of bread a day, only half toasted, and a good deal of greasy food, as he could get nothing else while traveling. He passes no more than three to three and a half pints in twenty-four hours. The examination of the urine to-day shows sp. gr. 1,016, faint trace of indican, no sugar, acetone, or diacetic acid. Permitted him to have in conjunction with his other food, lean ham, bacon, hominy, or any other cereal he may desire.

Case VII.—Mrs. A. S., 58 years old, native of Germany. Family history is negative as regards rheumatism, diabetes, cancer, etc. She had rheumatism and sciatica fifteen years ago, and has attacks of indigestion very often owing to indiscretion in diet.

About the fifteenth of last August she began to drink very much, have frequent micturition, and suffer from an intense itching of the genitals. To-day, September 3, she believes she has lost about ten pounds in weight, and feels very weak and tired, although her appetite is excellent. Her bowels move daily, but she complains of marked distension and gurgling. She has to get up a few times at night to pass water. On examination she appears all fagged out, shows some loss of flesh. Her eyes appear somewhat jaundiced, and her tongue coated. The report by the chemist on a twenty-four-hour specimen shows an output of 64 ounces, sp. gr. 1,041, some indican, glucose 5.5 per cent., and small amounts of acetone and diacetic acid. The urea is also very low, 0.8 per cent.

The patient was put on a culture of the *B. bulgaricus* 16 c.c. at a time, four times a day, calcined magnesia, a teaspoonful immediately before meals. Her diet consisted of tea and coffee without sugar, rice and oatmeal in moderate amounts, wheatena and sweet cream, soured milk, and buttermilk. She was also permitted broiled steaks, chops, and chicken, plain boiled beef and chicken, and the green vegetables. Also four slices of toasted bread a day. She was also given an orange, apple, or grape fruit.

September 12.—The patient feels very much better. The itch is still very distressing, but does not come on as often. She passed only 48 ounces of urine instead of 64. She does not drink as much, and is not as feverish. She has, however, lost one pound more in weight. She now weighs only 159, whereas her normal weight is 170. She also complains of restlessness and an inability to fall asleep. She does not have to get up as often during the night. The report of the urine shows a sp. gr. of 1,036, glucose 4.5 per cent., no acetone or diacetic acid. The same treatment continued.

September 17.—Patient feels very much better, but still somewhat weak. The itch is much better, drinks less, and only passed 36 ounces of urine in twenty-four hours. She does not have to get up at night to pass water; she also is not so restless. She is able to take a nap in the afternoon, and if it were not for the weakness she would not think she is ill. The examination of the urine shows a remarkable improvement. The sp. gr. is down to 1,025, the glucose down to 1.88 per cent. from 4.54, five days ago. The urea is up to 1.2 per cent., and there is still present a small amount of indican; treatment and diet the same.

September 24.—Has been very tired the past week, having had considerable physical and mental strain. She had had her house renovated and painted. She did not eat in time, and claims that she had some trouble with her water. The day when she began to collect her water she was all in. She, however, did not have to get up at night to pass any water. Passed 36 ounces in twenty-four hours. The report shows sp. gr. 1,031, urea down to 0.7 per cent., glucose up to 3.03 per cent., and traces of acetone and diacetic acid. There was also a considerable amount of indican. Here we see an increase in the indican is accompanied by an increase in the glucose, and a return in the acetone and diacetic acid. Treatment and medication same excepting that meat was cut down to once a day, at noon only.

September 28.—Patient gained one pound in the last week, feels very well. She had a bad cut on the finger, which healed up rapidly.

October 2.—Did not feel as well last night. Vomited yesterday and was troubled with a diarrheal condition all night. Passed a large mass of yellow mucus. The examination of the urine shows a marked improvement. Passed 36 ounces in twenty-four hours. The sp. gr. is 1,022, urea 0.9 per cent., no indican, glucose down to 1.05 per cent., and no acetone or diacetic acid. Same treatment was advised.

October 7.—Feels very well, but lost three pounds in the last week. The urine again shows a marked improvement. She passed 32 ounces in twenty-four hours; the sp. gr. is down to 1,017, no indican, acetone, or diacetic acid, and the sugar is only 0.15 per cent. Here again the disappearance of the indican is accompanied by a corresponding diminution in the percentage of glucose. The same treatment and diet ordered.

October 15.—Feels perfectly well. Has no pain or itch. The bowels are regular, she has no thirst, looks very well, and passed 48 ounces of urine in twenty-four hours. She is now taking four tubes of 16 c.c. of the culture a day. The urine is practically normal except for pronounced traces of sugar. The sp. gr. is 1,018, urea 1.4 per cent., no indican, acetone, or diacetic acid. Treatment same.

October 24.—Feels very well. Claims she never felt any better. The bowels are normal, and she sleeps very well. She passed 36 ounces in the last twenty-four hours. Specific gravity is 1,022, urea 1.5 per cent., no sugar, indican, acetone, or diacetic acid. As an addition to her diet she was permitted to have a baked potato, six slices of toasted bread a day, and the same amount of *B. bulgaricus* ordered.

October 27.—The examination of a twenty-four specimen again showed an absence of glucose; additional diet continued.

October 30.—Feels very well, gained about two pounds in weight. The examination of the urine shows a sp. gr. of 1,017, urea 1.3 per cent., no sugar, indican, albumin, acetone, or diacetic acid. Same treatment.

November 1.—Feels very well, gained another pound. She thinks she passed a little more water

than usually. The examination, however, shows nothing abnormal. The sp. gr. is 1,012, no sugar, acetone, indican, or diacetic acid. Same diet and treatment ordered.

November 4.—Feels very well. She thinks she passed about three and one-half pints of urine. The urine examination shows a sp. gr. of 1,014, no sugar, indican, acetone, or diacetic acid; she was permitted a whole potato and seven slices of toast a day in conjunction with her other diet.

November 10.—Is in perfect health. Has gained two pounds. Passes very much less water. Has been eating whole potatoes and seven slices of bread. Urine examination shows sp. gr. of 1,020, no sugar, albumin, indican, acetone, or diacetic acid. Permitted to eat poached eggs instead of hard boiled eggs, one whole potato, and to continue with the seven slices of toast.

The following case is of very great interest, first because the patient gives a very bad family history, a father and two brothers having died of the condition, and a brother and sister are afflicted with it now. Secondly, the length of time that the patient has the disease, namely, for a period of almost fourteen years, and, thirdly, because the "oatmeal cure" on which the patient was for almost two years had little or no effects on the condition. The sugar was somewhat reduced, but the patient developed large amounts of acetone and diacetic acid.

Case VIII.—M. E. B., age 56, native of U. S. Father died of diabetes twelve years ago. One brother died of diabetes and one died in a diabetic coma. Mother living and well. One brother and sister have the disease. He was never very ill until thirteen years ago, but claims he was told he had traces of sugar twenty years ago. Present illness dates back thirteen years. Began with polyuria and polydipsia and burning pains in the feet and toes. This became quiescent for a time, but two years ago he became very sick. Passed from 2½ to 7 per cent. sugar; acetone and diacetic acid; sp. gr. as high as 1,047. He was in the hospital for two months and while there received the "oatmeal cure" and since then, which was six months ago, is on an absolutely restricted diet and for three days every month goes on the oatmeal treatment. Does not eat any bread at all. Now complains of bad burning of the feet and ankles and in great toe of right foot. Toe nails fall off and ulcerate. Does not drink much and passes only 2½ to 3 pints. He has lost sixty pounds in the last two years. Falls asleep as he is talking. Examination shows enlargement of the liver, coated tongue, eyes icteroid, feet tender, nails red. Weighs only 164 pounds. Urine examination shows sp. gr. 1,027, urea 0.7 per cent., considerable amount of indican, sugar 0.66 per cent., large amounts of acetone and diacetic acid.

Treatment.—Was given 4 c.c. of the suspension four times a day. Calcined magnesia 3i t.i.d. before meals, and a fairly liberal diet, consisting of toasted bread, rice, oatmeal, green vegetables, broiled steaks, chops, chicken, oranges, apples, and grape fruit.

October 12.—Patient passes very much water, about six pints, but does not drink much. He gained five pounds in one week and feels very much better. Examination of the urine shows sp. gr. of 1,020, urea 1 per cent., small amount of indican, pronounced traces of sugar, no acetone, and traces of diacetic acid. A very peculiar condition. Treatment: 3i of bicarb. soda four times a day. Diet and other treatment same.

October 19.—Was not feeling as well in the last two days. He, however, gained five pounds more in the last week, making a gain of ten pounds in two weeks. Passed 4¼ pints. Headache not as marked. Has no pain in liver which he complained of at the beginning. Urine examination shows sp. gr. 1,024, urea 1.4 per cent., small amount of indican, sugar 0.36 per cent. No acetone or diacetic acid. Treatment same.

October 26.—Feels very well. Is now able to go out to look for work, while at the beginning fell asleep while talking. Passed 60 ounces in twenty-four hours. Has been out since 7 A.M. looking for work. Sp. gr. 1,030, urea 1.4 per cent., considerable amount of indican, sugar 0.92 per cent., no acetone, or diacetic acid. Has been rather lax with diet and treatment and under severe strain, which probably accounts for increase in sugar output. I believe he did not carry out his treatment, as the indican is very much increased.

November 9.—Feels very well. Has gained another pound. Weighs now 175 pounds, while he weighed only 164 when he started treatment. Now he has no burning in the feet except when it rains. Passed 56 ounces in twenty-four hours. Has no thirst, appetite good, is eating six good-sized slices of bread a day. Eats also oranges daily, rice and oatmeal, meat three times a day in form of chops or steak. Was put on doses of 16 c.c. a day. Urine examination shows sp. gr. 1,028, small amount of indican, sugar 0.06 per cent., no acetone, or diacetic acid.

November 16.—Feels well. In fact, feels the best that he has felt since sick. Has no burning of feet. Was not as well at the early part of the week because ate something that upset him. Examination of urine showed sp. gr. 1,029, urea 1.1, considerable amount of indican, sugar 0.28, traces of acetone. Same treatment and diet.

November 23.—Feels well; weighs same; sleeps well and eats well. Has some trouble, however, with his stomach, a sensation of fullness and distress after eating. Passed 2½ pints.

Urine examination of November 30, 1912, shows sp. gr. 1,018, urea 1.4 per cent. Small amount of indican, no sugar, acetone, or diacetic acid.

Case IX.—Mrs. R., aged 47, native of Russia. No family history of diabetes. Had diseases of childhood and repeated attacks of rheumatism in the past few years. Never had any serious illness that should confine her to bed.

Present history began about two years ago when she had a general furunculosis. Her urine was first examined September 30, 1911, which showed an output of 2½ quarts in twenty-four hours. Sp. gr. 1,032 and sugar 5 per cent. She was put on a fairly liberal diet including rice and oatmeal, broiled meats and fowl, green vegetables and toasted bread. She was also given the Bulgaricus culture 4 c.c. three times a day.

November 17.—Feels very much better. The urine shows the remarkable drop of sugar from 5 per cent. to traces and the specific gravity from 1,032 to 1,024, indican traces, uric acid, and calcium oxalate crystals. Same diet and treatment. This condition kept up until May 11, with varying success. At one time the glucose was up to 0.74, and at one time was even absent. The specific gravity came down to 1,014. The reason for this oscillation was because of her husband's condition and financial trouble. If business was better the sugar came down to a minimum, showing the influence the nervous system had on the output of

sugar. But at no time, as patient admits, did she follow out the treatment properly. At times she even forgot to take her medicine. She disappeared and did not show up for treatment until November 1, 1912, when she brought a chemist's report under date of October 2, with the following findings: Sp. gr. 1,020, urea 0.9 per cent., indican traces, sugar 1.08 per cent., and traces of acetone. No diacetic acid and a few uric acid crystals. She feels very well. Weighs to-day 140 pounds, which is her usual weight. She passed 60 ounces in twenty-four hours. Does not drink much. She has another report of October 30, with sp. gr. 1,021, urea 1.4 per cent., numerous uric acid crystals, small amount of indican, and sugar 1.05 per cent. She was put on original diet, and was given 4 c.c. of culture t.i.d. before meals and one on retiring.

November 9.—Feels very well, and claims she is following treatment closely. She, however, lost two pounds, which she thinks is due to worry, as she fears her daughter of 18 years has diabetes—(her partial history appears as Case 12). Urine examination shows sp. gr. 1,022, urea 1.5 per cent., sugar 0.46 per cent., no albumin, acetone, diacetic acid, or indican. Same treatment.

November 17.—Feels all right. Appetite very much better. She has had some rheumatic pains. Urine examination to-day shows sp. gr. 1,016, urea 1.2 per cent., sugar 0.24 per cent., no indican, acetone, or diacetic acid. Continue same treatment.

November 20.—Feels and looks very well. Does not believe she is ill except for report showing the sugar. Passed 1,560 c.c. in twenty-four hours, which is about normal. The examination shows sp. gr. 1,019, urea 1.6 per cent., traces of indican, sugar 0.15 per cent., no acetone, or diacetic acid. Treatment same.

November 27.—Feels exceptionally well. Passed 60 ounces in twenty-four hours. The examination shows the sp. gr. to be 1,018, urea up to 1.9 per cent., small amount of indican, and no sugar, indican, acetone, or diacetic acid. She will be kept on same treatment until normal diet is re-established.

Case XI.—H. B. G., aged 57, native of Ireland. Father and two brothers died of tuberculosis, one sister died of diabetes, and mother died of old age. The patient had all the diseases of childhood; delirium tremens a few years ago. At the present time drinks about a pint of claret a day, and uses considerable tobacco.

Present history dates back twelve years, when he suddenly began to drink considerably, and had marked polyuria. He also began to put on very much weight at first, but he has lost between 60 and 70 pounds since. He was a very hearty eater, and developed an enormous appetite, and suffered from severe constipation. He bloats very much after eating, belches considerably, and at times has very severe headache. He passes about two quarts of urine in twenty-four hours at the present time. On examination he shows a very badly coated tongue, eyes markedly jaundiced, a loud systolic murmur, evidence of general arteriosclerosis, and a blood pressure of 230. The urine examination shows a sp. gr. of 1,029, urea 1.6 per cent., sugar 1.54 per cent., small amount of indican, and no acetone, or diacetic acid.

He was put on 16 c.c. of a culture of *B. bulgaricus*, t.i.d. one-half hour before meals, was given a fairly liberal diet consisting of cereals, green vegetables, eggs, broiled meats, tart apple, and grape fruit. For his high blood pressure he was given 2 grains of sodium nitrite, t.i.d., and a purgative water in the morning.

November 16.—He feels very much better, is not as distressed after eating, and does not pass as much water. He passed only three pints in twenty-four hours. He feels very much lighter. His tongue is still coated and his eyes somewhat icteroid. His blood pressure to-day is down to 180. The urine examination shows the sp. gr. down to 1,024, traces of albumin, urea 1.8 per cent., sugar down to 1 per cent. as against 1.54 per cent. a week ago. His liver which was at first quite tender is still somewhat sore to pressure.

November 23.—He feels better than he did in twelve years. He says that he feels as if life is worth while living. He is not as thirsty, but does not sleep as well. His tongue is clearer, has no more distress after eating, and his blood pressure is down to 175. He eats five slices of toasted bread a day, steamed rice, oatmeal, or wheatena, broiled steaks or chops, and baked apple. His urine examination shows sp. gr. 1,022, urea 1.9 per cent., large amounts of indican, and sugar down to 0.32 per cent. Treatment and diet same.

November 30.—Feels very much lighter on his feet, and can get around very much easier. Passed three pints in twenty-four hours, tongue almost cleared up. The urine shows a sp. gr. of 1,023, urea 2.1 per cent., traces of albumin, small amount of indican, and traces of sugar. Treatment and diet same.

December 3.—Feels very well. Cannot believe he was ever ill. The examination of the urine shows a complete absence of sugar, hardly a trace of indican, and sp. gr. 1,020. He has increased his toast to six slices a day, the remainder of the diet being the same. His blood pressure is down to 173. The sodium nitrite was discontinued. The diet will be gradually increased until he will be able to eat everything.

Before proceeding with the consideration of the action of the *Bacillus bulgaricus*, and its influence on the diminution of glucose in the urine, let us glance over the theories and views held by observers as to actual cause of diabetes mellitus, and the pathology found to exist. Ever since the experiments of Von Mering and Minkowski,[1] wherein they produced an experimental diabetes in the dog by the extirpation of the pancreas, all observers to a greater or less extent have agreed that the pancreas plays an important part in the production of glycosuria. The investigations of Opie,[2] Cecil, MacCallum,[5] and others in this country, and Schmidt,[3] Ssobolew,[4] and others in Europe, have shown that in almost three-quarters of the cases of diabetes that came to autopsy changes in the Islands of Langerhans were found. In some there was a sclerosis. In others a hyaline degeneration, and in still others a hypertrophy in the remaining islands that had not become sclerotic. As a result also of the fact that the Islands of Langerhans have no connection with the ducts of the pancreas, it has been argued that the pancreas has an internal secretion.

All agree that the liver is the organ that makes the sugar, or fixes and stores the sugar that comes from the intestinal tract through the portal circulation, converting it into glycogen. Further, that the liver reconverts the glycogen into sugar as it exists

in the blood in sufficient quantities to meet the needs of the body. Also that in diabetes due to the pancreatic insufficiency, the liver either manufactures too much sugar, or is unable to fix and store it, or the tissues are unable to utilize it, as result of which it is excreted by the kidneys and appears as a glycosuria.

Von Noorden,[10] in his latest lectures on "New Aspects of Diabetes," contends that diabetes is not a single morbid entity. He claims that he cannot consider that diabetes is caused by a diminution or an absence of an internal secretion of the pancreas, to the exclusion of all other concomitant factors. The nervous system, the adrenals, thyroid gland, and hypophysis all have an influence to produce glycosuria to a more or less extent. He considers the action of the pancreas as inhibitory on the liver preventing the latter from reconverting glycogen into blood sugar, or permitting the glucose to go right over into the general circulation. He agrees that in almost all the severe cases there is a pancreatic insufficiency. But while this is true, there are also factors, as exciting impulses from the suprarenals, nervous system, thyroid, etc., which tend to influence the increase of glycosuria. When the inhibitory influence of the pancreas is diminished, the stimulating action of the adrenals, etc., may act on the "sugar factory" to an increased output of sugar.

Labbé[6] defines diabetes essentially as disease of the glucose-regulating apparatus, which includes the liver, pancreas, and the nervous system. Their function is to limit the production of glucose and prevent its accumulation in the blood and tissues. When diabetes is present, the tissues are unable to utilize and oxidize the glucose, and the liver, incapable of storing it and retaining it in the form of glycogen. So that glucose passes into the blood, causing glycosuria, etc. This process is present whether the lesion is in the liver, pancreas, nervous system, or pituitary gland. But this disturbance is not in the same degree in all.

Blumenthal[7] believes that normally the glucose is destroyed in the organism by a specific ferment, which is present in all the tissues, and which is favorably influenced by the pancreas in an unexplained manner. Further, that this glycolytic ferment is carried by the leucocytes to the muscles and here activated by the kinase-like substance provided by the pancreas, and that any disturbance either in the failure of the pancreas to provide this kinase-like substance, or by the absence of this glycolytic ferment, causes this glycosuria.

So also both Hirsch and Cohnheim[8] found that muscle and pancreas together destroy sugar, but not separately; Cohnheim ascribes this action to a specific ferment. Possibly the two organs provide a compliment and intermediary body, or the process is probably due to an action similar to the action of Pawlow's enterokinase.

A. Gilbert and P. Lereboullet[9] assert that in what they describe as the pancreatic form of diabetes, there is a sclerosis of the interacinous and intraacinous vessels which ordinarily attacks the Islands of Langerhans, and thereby causes an atrophy and sclerosis of these islands. When this is analyzed it is seen to be a sclerosis of canalicular origin due to an ascending infection. This infection is an autoinfection, and those having this condition usually suffer from digestive disturbances. In the pathological changes described by Opie and others, we find a sclerosis or atrophy in the Islands of Langerhans in most cases, while in others, a sort of compensatory hypertrophy exists; there is usually an accompanying arteriosclerosis, and some have reported a colloid change in the thyroid; cirrhosis of the liver, and sometimes a deposition of pigment in the liver causing what is known as "bronzed diabetes."

What does the *B. bulgaricus* accomplish, and how? In comparing the urine analysis of the cases reported and numerous cases that are still under treatment we find that indican is almost universally present excepting in three cases that have distinct causative factors. That means that with few exceptions we have a putrefactive condition of the bowels with the formation of indol, scatol, cresol, and phenols, etc., and other numerous toxic substances for which we have no known tests. Secondly, in eliciting the histories from the different patients, we find that almost all have been good hearty eaters, who were not very particular as to the quantity and quality of food and how often ingested. By quality here is meant not poor food, but the kind of food and how prepared. So that we find firstly an intestinal tract that is already the seat of putrefaction, as is shown by the indican, and secondly, the ingestion of food that is probably easily putrefiable. Then again we are struck with the fact that not until we get a reduction in the amount of indican do we get a diminution in the percentage of glucose, and in the cases where for one reason or another we have a rise in the percentage of glucose, we likewise find an increase in the amount of indican excreted. So that there must be necessarily a connection between the amount of putrefaction and the severity of the glycosuria. Carl Funck[11] found in cases that he reported, an intestinal putrefactive disturbance even in serious diabetic conditions, and touches on the causal relation between the production of indigo-forming substances and sugar excreted in all cases of supposedly gastroenteric origin. Of course we occasionally come across severe cases of diabetes with an excretion of a high percentage of glucose and no indican. In those cases I believe the reaction of the intestinal tract has been changed by different forms of treatment from an alkaline to an acid condition as putrefactive bacteria with few exceptions will not thrive in acid media (Metchnikoff[12] and Jarvis[13]). Then also after treatment has been instituted we will always get some indican sooner or later. There are cases that have a large output of glucose which has come on after operations, or the ingestion of toxic drugs for a long time. I have three such cases now under my care which exemplify the condition thoroughly. The following are brief histories, as they are not through treatment:

Case XI.—G. H., age 23, native of United States. Stenographer by occupation. Family history negative to diabetes. Had most of the diseases of childhood, and appendicitis two years ago.

Present history dates back to the time she returned from the hospital. She began to drink very much and had polyuria. Used to pass one gallon of water in twenty-four hours. Weighed before operation 152 pounds; now about 125. She never had any headaches, and her bowels, while usually constipated, would alternate with spells of diarrhea, pains, and cramps. At that time was told she passed between 8 and 10 per cent glucose. She has been under treatment since then. Was on a very restricted diet and took large amounts of codeine. Examination of urine to-day, October 6,

1912, shows sp. gr. 1,041, urea 0.6 per cent., faint trace of albumin, glucose 6.25, large amounts of acetone and diacetic acid, but no indican. She now is under treatment for four weeks and her glucose, which at one time, the first week after beginning treatment, was 7.14 per cent., is down to 3.71 per cent., and the urine only showed small amounts of indican once after she had upset her stomach.

Case XII.—R. R., age 18, native of United States. Father had traces of sugar last year. Mother suffering from diabetes two years and is now still under treatment. The patient had all the diseases of childhood, and goiter which was removed fifteen months ago, three months after it made its appearance. Patient began to lose weight immediately after operation and has lost fifteen pounds in that time. Used to weigh 118 pounds and weighs now only 103. She began to drink considerably, excessive appetite, polyuria, headaches, frontal in character. Bowels constipated, and since last week has an intense itch of the genitals. Urine examination shows sp. gr. 1,038, urea 0.6 per cent., glucose 6.25, no indican, acetone, or diacetic acid. Since her treatment the glucose has come down to 2.63 per cent., but her indican is still negative. This came down in ten days.

Case XIII.—H. M. S., Jr., age 9. Native of United States. Family history negative to diabetes. Had whooping cough at age of 4, influenza at 5, at which time heart was somewhat affected. Had myocarditis with distinct murmur. This lasted for a few months and then cleared up entirely. Since that time, especially toward evenings, would get peculiar attacks of cardiac arythmia, slow pulse, irregular in force and almost intermittent. Nothing organic, however, was found. It was pronounced to be caused by an autotoxemia. This antedated the glycosuria.

Present history dates back to about 1½ years ago, after taking resorcin with HCL, accidentally, for about a year. It was then noticed that the child had polyuria, passed about 100 ounces in twenty-four hours, and on examination sugar was found up to 4 per cent. This summer acetone and diacetic acid were discovered. The sugar has been as high as 7.14 per cent., and only on a few occasions was indican discovered. The child has been under treatment with the Bulgarian bacillus since July, 1912, and his sugar is now down to 4.35 per cent. He feels very much better, is able to get around, which he was unable to do for a few months. He is also beginning to take an interest in things.

The first of the above cases came on after a severe appendectomy which was performed under ether narcosis and which probably caused a parenchymatous degeneration of the liver. The latter is now enlarged and tender. Whether the pancreas is involved or not we have no means of ascertaining. We can only see that she is improving rapidly and that her sugar output came down from 7.14 per cent. three weeks ago to 3.71 now, with a complete disappearance of acetone and diacetic acid, which was very marked at the beginning.

The second case is interesting from the fact that the thyroid is one of the organs that is included in the sugar regulating apparatus. The thyroidectomy was done under local anasthesia. She, however, gives a bad family history, both father and mother having at one time or other had diabetes.

The third case, while he gives a distinct history of an autotoxemia, still seems to me to have been caused by the ingestion of the drug. He had the condition for over six months and no symptoms of diabetes appeared, and these symptoms did not appear until he had been taking the drug for about a year. Then again with very few exceptions the urine never showed the presence of indican, and with an autointoxication continuing for over a year and a half it should have shown some symptoms long before the glycosuria made its appearance.

Von Noorden, Cecil, Labbé, and others claim that the thyroid has some influence on the causation of glycosuria. But in spite of the fact that the first was probably caused by ether toxemia, the second due to the failure or diminution of an internal secretion of the thyroid, and the third due to an irritation of the liver, etc., to the ingestion of a drug, they are improving rapidly under treatment with the Bulgaricus. Coming back to the cases showing indican, we find that the sugar decreases coincident with the decrease in indican, while in the last three cases just mentioned we have a reduction in the percentage of sugar without indican being present. Then how does the *Bacillus bulgaricus* work?

I believe that the action of the bacillus is twofold: Firstly, that of destroying putrefactive conditions, and secondly in correcting and aiding in the proper metabolism of the carbohydrates. We know that the liver by its biochemic action neutralizes many poisons of the aromatic and alkaloid groups against amino acids and ammonia by the formation of urea, etc. The aromatic acids combine with sulphuric and glycouronic acid to form harmless substances and also absorb the aromatics, particularly phenol, scatol, and indol, products of putrefaction. Indol combines with the sulphuric acid of the liver to form indoxyl sulphate, which is then allowed to go over into the general circulation, where it combines with the potassium radicle in the blood to form potassium indoxyl sulphate, or indican, and as such is excreted by the kidneys. Now when putrefaction goes on for some time, perhaps years, what occurs? We get up an autointoxication due to the absorption of toxins formed at the same time as indol, skatol, and phenol, and for which we have no known test.. This process is very slow and insidious as only minute quantities are thrown into the blood at one time. This chronic autointoxication causes an effect on the nervous system manifested by marked irritability, hypochondria, insomnia, etc., interferes with the function of the thyroid gland, parathyroids, suprarenals, and perhaps the pancreas as we have marked digestive disturbances; causes also an endarteritis and arteriosclerosis, which is also very often an accompaniment of diabetes. It also causes a hepatic insufficiency shown by the augmentation of ammonia, uric acid, purin bases, etc., excreted in the urine. So we have here all the conditions that are also present in diabetes, or are considered as causative factors by Von Noorden, Labbé, and others, who consider diabetes as being caused by a disturbance of the sugar regulating apparatus which includes the nervous system, suprarenals, thyroid, pancreas, and the liver, where the sugar is stored and only reconverted into blood sugar to meet the needs of the body. Then may not the sclerosis of the Islands of Langerhans be also caused by the same autointoxication? Is it not possible that we have a fibrosis occurring in the pancreas as we have in the circulatory system, as the endarteritis and arteriosclerosis? Funck states that "constant deficient functions of the stomach as in achylia, and chronic intestinal diseases, re-

sult in demonstrable pathological changes of the pancreas." A. Gilbert and P. Lereboullet, as quoted previously, claim that there is an ascending autoinfection of canalicular origin which attacks the Islands of Langerhans and causes a sclerosis and atrophy of same, and that this condition is present in people suffering from digestive disturbances. Is that not a condition that is present in autointoxication? So that the *Bacillus bulgaricus* by inhibiting putrefaction and destroying the putrefactive bacteria overcomes this autointoxication and thereby gets rid of the substances causing an irritation and disturbance of the sugar regulating apparatus.

The second thing accomplished by the *Bacillus bulgaricus* is in aiding or correcting starch metabolism.

In a series of tests made by me on starch digestion by pancreatic juice, both that of the dog and man, and carried out for a period of several weeks, I found that the digestion of the starch goes on very much slower in the presence of the *Bacillus bulgaricus* than when pancreatic juice alone was used. The bacillus generates free lactic acid, and in order to see whether this bacillus alone or the acid it generates interferes with the digestion, a solution of lactic acid, of similar strength to that present in the culture, was used with the same result as to the starch digestion. In other words, the Bulgarian bacillus generates the free lactic acid, and it is this acid condition of the bowels that interferes with the rapidity of the starch digestion. By thus lengthening the time it takes for the carbohydrates to be converted into dextrose very much less sugar is thrown into the circulation and very much less is to be excreted by the kidneys, until a tolerance is established for the carbohydrates. This goes on slowly until a normal tolerance is reached.

The following table shows what has occurred in the test mentioned and the actual time it took for the conversion of starch into glucose when the bacillus was used, when pancreatic juice alone, and when free lactic acid in same strength as the suspension was used. This table is one of a great number that has been made in conjunction with these tests. The test tubes with the solutions were kept in an incubator at 98.6° F. In some of the tests made I used blood serum and feces to activate the pancreatic juice, but the digestion was very rapid, and while the same conditions occurred as indicated below, the data obtained had to be taken in about a half hour, and the contrast was not as marked as in the one shown here.

| MIXTURE | 10:00 A.M. | 11:00 A.M. | 1:00 P.M. | 2:00 P.M. | 6:00 P.M. | 10:00 P.M. |
|---|---|---|---|---|---|---|
| 1. Boiled starch, 10 c.c. Pancreatic juice, 1. c.c. | Blue black reaction with iodine | Reaction to iodine somewhat lighter verging on violet | Faint reaction to iodine | Very faint reaction to ioidne | Does not react to iodine | Does not react to iodine |
| 2. Boiled starch, 10 c.c. Pancreatic juice, 1 c.c. Suspension B. Bulgaricus, 1. c.c. | As above | No change, blue black reaction to iodine | Gives violet blue reaction to iodine | Violet reaction to iodine | Purple reaction to iodine | Faint reaction with iodine |
| 3. Boiled starch, 10 c.c. Pancreatic juice, 1 c.c. Lactic ac. sol., 1 c.c. | As above | Blue black reaction to iodine | Gives violet blue reaction to iodine | Violet reaction to iodine | Purple reaction to iodine | Faint reaction with iodine |

Whether this lactic acid produced by the *Bacillus bulgaricus* also stimulates the internal secretion of the pancreas (the internal secretion is that which is supposed to inhibit the action of the liver in manufacturing more sugar, and allow it to go over into the general circulation), I cannot say. But I do know that in two cases where I gave dilute hydrochloric acid, and dilute nitro-muriatic acid in conjunction with the *B. bulgaricus* for a few weeks, the percentage of glucose increased, and when I went back to the bacillus alone, the percentage of glucose immediately began to decrease.

It may be true, as has been demonstrated by Pawlow, that an increased acidity of the intestinal tract causes an increased output of pancreatic secretion, and this is perhaps what occurred when the dilute hydrochloric acid and the dilute nitro-muriatic acid were given, and we got an increase in the percentage of glucose, showing that at least the amylopsin was increased. But the lactic acid generated by *B. bulgaricus*, as was demonstrated by the foregoing tests, slowed down and prolonged the time for the conversion of the starch into glucose.

*Conclusions.*—1. While we all agree that in cases that have come to autopsy, there are changes in the pancreas especially in the Islands of Langerhans, and that these changes are probably present in all cases of diabetes, with perhaps irritation and changes in the suprarenals, thyroid, nervous system, and hypophysis, still these changes are also caused by an autointoxication.

2. That in cases where there is no indican in the urine and no autointoxication we usually have definite causative factors producing the glycosuria as in thyroidectomy, ether narcosis with a probable parenchymatous degeneration of the liver, etc.

3. That in the majority of cases the indican output is in close relation to that of the sugar.

4. That by correcting and curing the autointoxication we remove the irritating influences on the sugar-regulating apparatus.

5. That *B. bulgaricus* destroys putrefaction and so overcomes the autointoxication.

6. That the bacillus changes the reaction of the intestinal tract from an alkaline to an acid condition.

7. That carbohydrate digestion is inhibited or is rather very much slower in the presence of this lactic acid.

8. That by thus lengthening the time of carbohydrate digestion only small amounts of sugar are formed and absorbed.

9. That by permitting only small amounts to be formed and absorbed, we gradually increase the tolerance for carbohydrates until a normal tolerance is established.

# GONORRHEAL RHEUMATISM IN ARTHRITIC SUBJECTS.

## ITS CLINICAL FORMS AND THEIR TREATMENT.

By JEAN DARDEL, M.D.,

AIX-LES-BAIN (SAVOIE) FRANCE.

It may surprise the younger generation of practitioners to find that our knowledge of gonorrheal rheumatism practically dates back not more than twenty years. Since this protean affection gained for itself a place in nosology, clinical observation has gradually extended its sphere of influence and has made us familiar with its various clinical forms, from acute phlegmonous suppurative arthritis to chronic arthropathies of the rheumatoid type and rhizomelic vertebral ankylosis.

It must be admitted, however, that throughout the past century observers have suspected the existence of pseudo-rheumatism, side by side with the ordinary acute, frank, febrile, articular rheumatism. Bouillaud, for instance, as far back as 1840, applied the term pseudo-rheumatism to the joint affections met with in the course of various infectious diseases. Unfortunately, there was a good deal of confusion at that time between the different infections that gave rise to these articular manifestations, so that, although they suspected the existence of various "rheumatisms," they were not in a position to decide what was really acute articular rheumatism and what pseudo-rheumatism. We must, therefore, not be surprised to find that Bouillaud described as true rheumatism certain suppurative arthrites which, we now know invariably to belong to the group of pseudo-rheumatisms. Later Besnier proceeded on the same misleading lines, and Lasègue did his best to differentiate suppurative arthritis from true acute rheumatism, but their views did not commend themselves to contemporaries. At the Medical Society of the Hospitals of Paris, in 1866 and 1867, a debate took place on the subject which remains memorable in the history of medicine. The theory of pseudo-rheumatism, especially with regard to that of gonorrheal origin, carried the day in opposition to that of simple coincidence, but no agreement was arrived at as to the real cause of the arthropathies. Peter ascribed them to a manifestation of the common rheumatic diathesis under the influence of the gonorrheal poison. Fournier and Féreol maintained the gonorrheal origin, but Fournier was not disinclined to accept the existence of a reflex rheumatism of urethral origin, while Féreol rightly asserted its infective virulent character.

This is how matters stood until 1881, the date at which Bouchard delivered the course of lectures in which he defined the characters of pseudo-rheumatism and summarized his views in the following words: "All infectious diseases may present among their manifestations accessory articular manifestations distinct from true rheumatism and dependent upon the general infection of the economy."

The discovery of the gonococcus by Neisser in 1879 and the conception of infective pseudo-rheumatism promised to clear up the question. Such, however, was not the case. Discussion was resumed on the mode of action of the gonococcus on the joints; some observers who had only rarely discovered the gonococcus in the inflamed joints asserted the toxic nature of the arthropathies, an opinion which, as we shall show later, deserves to be rehabilitated in respect of chronic rheumatism; while others, having identified the staphoylococcus and the streptococcus, either alone or associated with the gonococcus, admitted the secondary nature of the acute pyarthritides. These discussions went on until the researches of Deuchmann, Landsmann, Vaquez, Stern, Jaquet, and Quéyrat showed the gonococcus to be invariably present when properly searched for in the articular fringes of the joints, in the course of arthrotomy, or by puncture by scratching the fringes with the needle.

It is now generally admitted that in most instances gonorrheal rheumatism is due to the localization of the gonococcus in the joints. We use advisedly the words "in most instances" instead of invariably, because it seems probable that a certain number of secondary infections give rise to acute pyarthritis, while, on the other hand, certain cases of chronic rheumatism running a slow apyretic course without any previous acute attack, may also be due to intoxication by the gonococcal poison acting on the joint structures or on the nervous system (rheumatism of nervous origin), possibly also on the vascular glands, especially the thyroid body. Certain instances of improvement of the joint manifestations consequent upon the administration of thyroid extract in cases of chronic gonorrheal rheumatism strongly suggest the view that the visceral damage may react secondarily on the bony system.

The clinical forms of gonorrheal pseudo-rheumatism, both acute and chronic, are very numerous. One of the most remarkable is the acute form simulating ordinary, acute, articular rheumatism. As a rule it is toward the end of an attack of gonorrhea, during the third, fourth, or fifth week, or, it may be, in the course of chronic gonorrhea, gleet, that the rheumatic manifestations supervene. The temperature rises and the joints become involved, but the difference between the true and false rheumatism is plain from the outset. In the latter there is wanting the red sore throat which is commonly present in true rheumatism. Then, too, each variety of rheumatism has its joints of predilection. In gonococcal pseudo-rheumatism we get, in the order of decreasing frequency, the hip, the knee, the smaller articulations of the foot, fingers and hand, the shoulders, and the sternocostal and temporomaxillary articulations. To begin with, a large number of joints are involved; those of the fingers, for instance, the knees and hips; then, in a second phase, the infection quits a certain number of them and tends to localize itself in one, two, or three parts.

Acute rheumatism, in fact, is polyarticular *ab origine;* whereas the other, though the onset may be polyarticular, soon becomes oligoarticular and settles in certain joints of predilection: the knee, the hip, the articulations of the fingers and the wrist. The temperature, high at the beginning, often remains at or about 100 to 100.5° F.; the urine is thick and high colored, but albuminuria is rarer than in true rheumatism. There are no acid sweats and no anemia as in ordinary rheumatism,

and the general health is much less affected. Locally, the joints are swollen, enlarged, and dematous; the spontaneous pain soon diminishes and becomes trifling, but is provoked by movement and is particularly severe when pressure is brought to bear on the ligamentary and scapular attachments inside and outside the femoral condyles, on the tibial and peroneal attachments of the lateral ligaments of the knee, the tibial and peroneal malleolæ in the arch of the foot, and, similarly, in the corresponding points in the joints of the upper limb. Slight intraarticular effusion is the rule. Sometimes, especially in the knee, it may be abundant, so much so as to distend the *culs-de-sac,* which then project beneath the skin. This state of tension is fatal to repose and causes distressing insomnia. Puncture of the lateral *culs-de-sac* affords great relief, and may be resorted to without hesitation provided it be done with the necessary antiseptic precautions. The liquid withdrawn is rather thick, of a greenish hue, is very fibrinous and readily coagulates. It contains leucocytes and polynuclear cells in more or less abundance. If the fluid is turbid and the polynuclear leucocytes obviously damaged (Widal), suppuration is to be apprehended.

The evolution of this form of rheumatism is often rather grave and our prognosis should always be guarded. Recovery without sequelæ is rare, and in most instances the arthritis tends to become chronic, with more or less ankylosis accompanied by amyotrophy of the crural when the joint affected is the knee and the calf muscles when it is the arch of the foot. These resist massage for a long time and greatly interfere with walking for weeks or, it may be, months. We are always justified in apprehending suppuration, even in the polyarticular forms. There is another generalized form characterized by vague pains in the joints, in the arch of the foot, and in the fingers and wrist. These are superficial and not spontaneous, and are excited by deep palpation over the capsular insertions and articular ligaments. These pains hinder walking, but they are often less severe during the daytime than on resting. Fournier used to say that the patient "unrusted his joints." The prognosis is benign so far as life is concerned, but these arthralgic forms are troublesome by reason of the tenacity and their refractoriness to treatment.

Lastly, there are monoarticular forms limited to the arch of the foot, the hip, but most frequently to the knee, manifested by hydrarthrosis setting in suddenly or coming on insidiously, pseudo-phlegmonous or even suppurative. Even more than in the polyarticular forms these monoarticular forms of acute arthritis become grave on account of their tenacity and their ankylosing tendencies. It is in the cases of suppurative arthritis described by Duplay and Brun and Lapersonne that we are apt to meet with the constitutional complications such as gonococcal endocarditis and meningitis which usually end fatally. Then, too, we must not forget that in the severe forms which end in ankylosis, instances are on record of secondary tuberculous infection of tissues previously damaged by the gonococcus.

Independently of these acute forms there is a chronic form of rhemuatism consequent upon either an acute or subacute attack of joint inflammation, or it may be primary. It may assume the appearances of rheumatoid or pseudo-gouty arthritis involving the fingers and smaller articulations, which swell and undergo deformation by reason of fibrous retraction until they come to look like bunches of carrots. It may attack the joints of the foot, causing talalgia, osteitis of the calcaneum or bony deformities giving rise to Fournier and Jacquet's gonorrheal flat foot.

Lastly, among the graver manifestations of chronic rheumatism may be mentioned rhizomelic spondylosis investigated by Pierre Marie, the gonorrheal origin of which appears to be fairly common. This disease entails complete welding together of the vertebræ with kyphoscoliosis of the cervicodorsal region. At the same time the shoulders and hips become ankylosed, though in some instances they are not affected, in which case we are dealing with the gonorrheal non-rhizomelic form (Guillain and Laroche).

In all these acute or chronic forms of arthropathy, muscular atrophy is the rule, and when well marked may introduce an element of gravity which has to be taken into account in formulating a prognosis. In some cases the amyotrophy is so pronounced as to dominate the scene. This is the amyotrophic variety described by Klippel, which, after all, is extremely rare. Side by side with the joints the synovial sacs and the serous bursæ may become involved, the bones may be the seat of osteitis and the skin may present various lesions: erythema nodosum, polymorphous erythemata, vesicular erythema and even that curious lesion known as Jacquet and Chauffard's gonorrheal keratosis. All the organs may be attacked by gonorrheal septicæmia, and it is in these grave forms that it has been possible to demonstrate the presence of the gonococcus in the blood of the patients. We may add, moreover, that these cases are exceptional when we bear in mind the great frequency of mild attacks of gonorrheal rheumatism.

The treatment differs according as we are dealing with acute or chronic rheumatism, and we will discuss these separately.

Acute polyarticular rheumatism is treated during the febrile stage by the administration of salicylate of sodium, a dram or a dram and a half in the twenty-four hours, or by aspirin, 20 to 30 or even 40 grains. These drugs may cause more or less gastric intolerance with nausea, vomiting and diarrhea in patients with delicate stomachs, but not infrequently this intolerance is due to defective methods of administration. Large doses of salicylate of sodium, for instance, require to be freely diluted in a large quantity of water (plain water or an aromatic infusion) so as to obviate irritation of the gastrointestinal mucosa. Sometimes, without its being in our power to offer any explanation of the occurrence, the salicylate treatment causes a sudden retrogression of the painful and pyretic manifestations and the axiom, once universally recognized, that the effect of the salicylate established the differential diagnosis between ordinary and gonorrheal rheumatism, must not be construed literally. This treatment, however, often proves unavailing, and not infrequently the symptoms run their course unchecked by the measures brought to bear. Aspirin seems to be the most active of the group, and when it fails, we must have recourse to other members of the antineuralgic group: antipyrin, pyramidon, quinine, etc., although this purely symptomatic medication has no influence on the underlying cause of the articular manifestations. Locally, apart from the employment of analgesic applications and counter-irritants, certain forms of gonorrheal arthritis call for special interventions. When the effusion

into the joint is copious enough to cause intolerable pain and persistent insomnia or threatens local mischief such as dislocation, rupture of the synovial membrane or spontaneous luxation, we must have recourse to puncture, repeated if necessary, in addition to active counter-irritation. As soon as the acute symptoms have subsided, early passive movements and massage will combat the tendency to ankylosis displayed by gonococcal arthropathies. In this way we may hope to avoid the "fixation in a good position" in a half gutter plaster splint recommended by surgeons, the object of which is bony ankylosis of the articular surfaces. It is only in the suppurative and exceptionally grave forms that we should have recourse to arthrotomy, either simple or followed by the application of iodine or chloride of zinc. Until quite recently these measures summed up the therapeutic means at our disposal.

Recent research has added a whole series of agents, some of which are still at the period of observation, but which should nevertheless be given a trial when the classical methods of treatment prove useless. To begin with, we have antigonococcic vaccination, brought forward in England by Wright,[1] who invented the method; by Maute,[2] and by Mainini.[3] It consists of the injection of dead gonococci, which causes the formation in the patients organism of antibodies which assist in establishing immunity. Wright's gonococcic vaccines are in the market and can be employed when for any reason it is not practicable to prepare a vaccine from the patient's own gonococcus. These vaccines are titrated, and it is easy to inject the dose of gonococci desired. At the onset Wright used to advise one to ascertain the opsonic index of the patient's serum, *i.e.* to ascertain the activity of the substances that assist phagocystosis. He had remarked that after an injection of gonococci these substances diminished in the serum for a time, subsequently rising to a higher level than that existing before the injection, and his plan was not to inject vaccine a second time until the subsidence of the negative phase. Unfortunately the opsonic index is a delicate matter, and it really does not appear to be indispensable. Mauté advises the first injection of 25 million gonococci, followed by a similar number four days later and 50 millions every five or six days thereafter. These injections are made into muscle and rarely give rise to any local or constitutional disturbance. In favorable cases the joint pain diminishes, the hydarthrosis undergoes absorption and the fever disappears. Unfortunately these effects are often conspicuous by their absence, and in any case chronic rheumatism is not amenable to the method. Still, in view of the innocuousness of these injections we can always give them a trial in grave cases, the only contraindication being too depressed a state of the general health which might render it unable to resist the vaccinal reaction. Apart from vaccination, mention must be made of seropathic methods. Rogers[4] (1906) employed in man an antigonococcus serum which is not as yet on the market. Failing this we might try antimeningococcic serum as recommended by Pissavy[5] and by Raymond and Chiray[6] in 1910 and 1911. The method consists in injecting 30 cc. of the Dopter and Flexner serum beneath the skin and repeating the injection every other day. In some instances these observers have noted the disappearance of the pain and effusion, thus enabling the joint to be early moved and obviating ankylosis. This treatment also seems to exert very little action on the chronic forms.

In this direction there remains the autoseratherapeutic method long since applied in the treatment of ascites and bacillary pleurisy. According to cases reported by Benasson and Ramond the method appears to be perfectly inoffensive. It consists in withdrawing some of the articular fluid and injecting it forthwith into the connective tissue to the extent of from 10 to 20 cubic centimeters either near to, or distant from, the affected joint. Ramond indeed has gone as far as to inject pus from a suppurating arthritis (1 to 2 cubic centimeters) after merely ascertaining by microscopical examination the absence of microbial elements. These observers are of opinion that the method makes for the absorption of the articular effusion, and it might be given a trial in cases with abundant effusion that recurs after repeated puncture.

On somewhat different lines are radiotherapy, thermotherapy and Bier's method, which may all be tried in obstinate arthropathies. With regard to radium, Dominici and Gy[7] have taken the matter up afresh quite recently, and they state that under its influence the pain diminishes rapidly and early movement may be resorted to, ankylosis being thus avoided. It is remarked, however, that the big joints are more resistent than the small ones and that in spite of rubber screens and paper placed between the skin and the x-ray apparatus one is apt to get superficial burns which, for that matter, heal readily enough.

In lieu of these forms of apparatus which are difficult to manipulate we may make use of radioactive mud (A. L. Renault,[8] Claude[9]) or radium poultices (radioplasm). This mud contains radium, lactium, and uranium. A thick layer of the mud is spread over the skin covering the joint, a layer of wadding is applied on the top of this, and the whole is maintained in position with a bandage for from six to twenty-four hours. The dressing is renewed daily for from eight to ten days. In some instances slight cutaneous erythema has been produced, necessitating suspension of the treatment. We might endeavor to prevent this by interposing a thick layer of gauze between the mud and the skin.

In conclusion, some reference must be made to injections of radium salts as made by Chevrier into the joint after the latter has been evacuated by puncture as completely as possible. Chevrier employs a solution prepared in accordance with the indications laid down by Dominici, injecting from 20 to 50 micrograms into each joint. He claims to have obtained favorable results especially in acute cases attended by much inflammation.

Bier's method has for object the production of passive venous hyperemia in the affected limb. For this purpose we may make use of a rubber band which is wound about the limb at a distance of about five inches above the sick joint. It must be tight enough to partially prevent the return of the venous blood, but not tight enough to interfere with the flow of blood in the arteries. Under these conditions the limb becomes hot, swollen, and of a fiery-red color (Bier). The band is removed in an hour or so, and the sittings can be repeated every day or every other day. Bier, Joseph,[10] and Hofmann[11] claim to have obtained excellent results from this treatment, but Hirsch[12] and Robin[13] failed to discover any benefit from it.

The hot-air treatment seems to me to be far more trustworthy, whether by means of douches or by placing the joint in a hot-air box. The temperature in the latter may be raised to from 175° to 210° F. for from half an hour to an hour at a time.

The limb is then seen to be covered with perspiration. It must be gently wiped and wrapped up in flannel so as to avoid a chill. The hot-air treatment is much easier to apply by means of electrically heated apparatus which enable us to obtain a much higher temperature while allowing of periodical inspection of the skin to see how it reacts.

Hot air has the advantage of being applicable at the patient's own home, but when possible even more satisfactory results are obtained by hydrotherapy; that is to say, the hot-water or hot-vapor douche. As applied at Aix-les-Bains the natural mineral sulphur water at a temperature of from 105° to 110° F. is applied in the form of a local douche for ten or fifteen minutes followed by appropriate passive movement and massage. In the Berthollet or vapor bath the limb is immersed in the atomized hot water for twenty minutes or so, then passive movement may be used, and also massage. This is indeed the classical method of dealing with joints that are partially ankylosed or are the seat of a low form of chronic inflammation. It is obviously inapplicable in recent and acute cases. Aerothermotherapy constitutes an excellent revulsive, and serves to diminish pain. Associated with massage it is unquestionably the most active method at our disposal for the treatment of refractory cases of arthralgia with or without ankylosis.

The chronic forms of gonorrheal rheumatism, in addition to the methods of treatment set forth above, in some instances call for special therapeutic measures. From the general viewpoint we must disinfect the genitourinary canal, and it should be borne in mind that many of these obstinate cases are consequent upon slight uterine affections or chronic urethroprostatitis. The local treatment of these affections is even more important than that of the inflamed joints. On the other hand, Leopold Lévy, Parhac and Papiniau and Viola have published notes of cases in which very marked improvement followed a course of thyroid treatment which, as we know, exerts a wonderfully good effect in certain cases of ordinary chronic rheumatism. We can therefore administer two-grain cachets of thyroid powder, from one to three to be taken daily, suspending the treatment in the presence of symptoms of intolerance. Lastly, from the local viewpoint, when the joint has become deformed, one might try the effect of thiosinamine or fibrolysin injections; for example, 2 cubic centimeters of the latter daily for a fortnight. Associated with massage and passive movement of the joint this method is capable of yielding very good results, though in the hands of Ramond and Chiray it does not seem to have proven satisfactory.

## THE SANATORIUM OR THE HOME?

By L. ROSENBERG, M.D.,

BEDFORD HILLS, NEW YORK.

MEDICAL SUPERINTENDENT OF THE MONTEFIORE HOME COUNTRY SANITARIUM.

The earlier period of the open-air treatment of tuberculosis in specially built sanatoria was frequently accompanied by extravagant claims for this mode of treatment, and often enough the public and the profession were led to entertain unwarranted expectations from the method. But it did not take very many years for this unduly roseate outlook to wane; the sobering influence of rapidly accumulating experience cleared the atmosphere very considerably; physicians engaged in the management of the disease learned to temper their claims for its merits by a wise conservatism, which was founded upon a better conception of the limitations of all methods and a more accurate knowledge of the type of cases in which benefit might be expected. The medical and lay world had arrived at a pretty accurate appraisal of the virtues and shortcomings of the newer system of cure; and in the last decade much energy and treasure have been devoted to further the scope and activities of organizations for the cure and study of tuberculosis. These efforts rested, and still rest, upon what is regarded the proven value of segregating sick individuals where they may obtain enlightened control and a precise, detailed regimen.

Our complacency received some rude jolts by the publication in the last few years of articles setting forth the alleged failure of methods which were regarded as the best that could be devised in the present state of knowledge and human endeavor. We were told that all our efforts and money had been expended in pursuing an *ignis fatuus;* that the end gained was nil as compared with the work and sacrifices involved in the undertaking. This was a cue for many partly informed individuals to put forth the claims of the stay-at-home policy, which, it was asserted, was capable of yielding as much good and requiring far less financial and other strains than the much-vaunted sanatorium treatment.

Surprising outcomes in cases denied the best environment occur frequently enough, and to some observers it seemed that there was justification for the anti-sanatorium attitude. We are all willing enough to concede the appositeness of the invariable argument used—the wrench from loving relatives and the cheerfulness of the family circle entailed by residence in a sanatorium; the saving of money; the avoidance of that tendency to institutionalism which so often accompanies the more popular form of treatment, etc.

If it could be even approximately demonstrated that the limited advantages of the home treatment offset those which are inherent in a "cure" pursued away from home, in formal institutions especially equipped for this one purpose, nothing further could be said. This has not only been done but contrary evidence is furnished by the very large number of patients who come to sanatoria after fruitless attempts to regain their health at home or away from home in unsupervised surroundings. The only lesson that the "home" treatment teaches is a realization of the gravity of the disease and the rapid havoc it may produce when the attempt is made to cope with it by any means save the methodical routine of an institution.

Were tuberculosis a disease of the prosperous, the well-to-do or the wealthy, a great deal more force would be given to the plea for the home as a fit place to subjugate an insidious enemy. Patients might more often be allowed to undertake the "cure" under their own roof-tree, or upon it. We physicians know well enough the sweet potency of gold in smoothing the pathway of the invalid, of conserving health, and in the right hands of fostering happiness. No one will gainsay that everything being equal, the tuberculous individual with means has a cruel advantage over his less fortunate brother. But it is so glaringly evident that the disease is most prevalent in those poorest off in worldly possessions! And how can we entrust the management of a difficult matter to those unfortunates who are not alone indigent but very often, as a corollary to their poverty, deficient in the enlightenment which is essential for the needed cooperation?

The financial aspects of the subject have been graphically depicted by Professor Irving H. Fisher, and his deductions have been accepted as well within the mark by most observers, medical and sociological. The mass of the sick tuberculous is made up of people of very slender resources and very often absolutely no resources at all. The attempt to restore such to the ranks of industrialism by means other than a sanatorium treatment—at least for a definite portion of time until the most menacing symptoms have been successfully overcome—must remain an uncertainty, a makeshift, incomparable in efficacy with what obtains in the systematic recourse to the dietetic-hygienic treatment as carried out in sanatoria throughout the world.

It is quite true that instances of recovery at home are observed—but not nearly so often as the tragic failures. Every physician and social worker in New York must concede this, for it is in evidence every day. Surprises greet us all the time in the treatment of this as well as other diseases. But surprises are not guide posts from which to take the right path, and we do not want to depend upon uncertainties when we go in for a fight. "The Lord is on the side of the man with the heaviest armaments" is an expression attributed to the cynical but profound Corsican, and we who are armed for the fray, no matter how imperfectly, are certainly better equipped for victory than those who spurn our chief accouterments.

The "home" treatment is supposed to resemble that pursued in the sanatorium in three cardinal things. If it were only ideal it would be the sanatorium treatment transplanted to the inglenook. These principles are fresh air, rest, and alimentation. I very much doubt if there exist many homes in which the first two can be even approximately brought near that completeness possible in a well-regulated institution. The home circle is not the place for such an experiment. Indulgent relatives and friends will see to it that there is not too much rigor in the one or the other, according to their lights, even if the temperament of the patient would make for complete docility, which is seldom enough the case. What can be said in favor of the best-intentioned ministrations of relatives, with a periodical visit from the family physician—though he be ever so accomplished—as against the daily, minute supervision which is exercised by sanatorium physicians and nurses trained in the management of such patients? And trained, too, in the subtle windings of the psychology of the chronically ill, who have to be both humored and repressed, observed and guided like children, and steered clear of the many pitfalls that encompass them!

We have figures as to the results of the sanatorium treatment of tuberculosis, just as we have data as to other measures in medicine and surgery. While it is quite the fashion to sneer at statistics, and although I grant that there are many fallacies that beset an inquiry relying too much upon figures alone, I do not know what medicine would be without the careful tabulation of cases and the results of treatment which form such an important item in modern science. We do not acknowledge ourselves fetish-worshippers when we make inferences from such sources.

Now the most conservative figures published by institutions situated in widely separated parts of the world and under varying climatic conditions give on the average of from 75 to 80 per cent. of improvement in health in cases treated; the betterment is classified in grades, from "apparently cured"—a term falling into disfavor—down to simply "improved." It is unfortunately true that we do not yet know the end-results in these differently classified cases; but this is a defect that inheres with still greater moment in the home treatment. It must not be lost sight of that the end-results do not depend upon the sanatorium except to a slight degree—the potent influence must always be in the home and social circle in which the discharged patient finds himself. If these influences are salutary so much the better the chances of the patient retaining that which has been gained. The sanatorium should not be held in default, therefore, if in a given case the final outcome is not as good as the classification upon discharge. Too many factors enter into the after-history of patients to make it possible for the sanatorium as now constituted to cope with them. But we have the right to utilize the sanatorium figures of results as indices of the possibilities, since these patients may be presumed to illustrate the tendency of nature to heal when given the proper assistance by man-made measures.

So far as I know no such statistics are available for the study of the effects of the home treatment. If such are kept by individual observers they must needs fall far short of that sufficiently imposing array which come under the ken of the institution physicians. I do not think there are many physicians in the cities who have constantly under close daily observation a hundred, two hundred and even three hundred people suffering from tuberculosis in various stages. I doubt, too, if they have at hand for careful study a daily record of the temperature and pulse rate, the quantity of the sputum and its bacillary content, whether these are constant or

fluctuating, regressive or progressive, the record of weight, the personal observations as to appetite and table habits, the peculiarities of patients' dietetic tastes, the method of eating, of playing, of resting, of exercising, of sleeping, and so on indefinitely in all the ramifications of daily life. The conclusions of men situated to do these things are certainly of value, and their opinion is overwhelmingly in favor of some closely regulated form of supervision, most feasible in a well-equipped sanatorium.

Most of the men connected with the institutional treatment of tuberculosis are conservative in the estimates which they make of the ultimate good accomplished. We are not unduly confident. We realize fully that to classify a patient as "arrested" is not the end of the song by any means. Only too often we discover the result to be not enduring. But again be it said, this puts no blame on the sanatorium, nor does it strengthen the claims of the home. A great number and variety of unfavorable factors are at work to vitiate the good that the sanatorium has accomplished. First and foremost is poverty; next perhaps comes weakness of character, and then we have to consider weakness of the body; when the last two are combined the struggle is hopeless. Our socialist friends like to blame what they call "The System" for most of the miseries of mankind. Certain it is that the modern organization of society makes the struggle for existence at times inhumanly keen for the able-bodied and energetic ones; and to this unequal struggle many tuberculous convalescents are compelled by necessity to return; its effects upon the benefits derived from a provisional course of sanatorium treatment are often blighting; and we are therefore all the more bound, in duty to our unfortunate fellow-beings, to increase the means of overcoming a tragically widespread disease and strengthening the resources which are at our disposal. This cannot be done by the home treatment—we must fight a highly dangerous enemy by counter-organization, and not revert to the individualistic type of existence of early times—when men were said to be better and happier, as to the truth of which I know not.

But the home treatment has its place, and a highly important one it is, in the post-discharge regulation of tuberculous individuals. When the time comes to make this possible in a systematic and thorough manner, on a necessarily gigantic scale, we shall hear less of the limitations of the sanatorium treatment, and the so-called home treatment will take its proper place in the battle line—a valuable rear-guard against surprise and a reserve force to fortify the positions taken in the earlier engagements. Those interested in the modern treatment of tuberculosis are beginning to realize the necessity for supplementing the sanatorium course with some form of post-discharge regulation of the patient. In some parts of the world this has been begun by the formation of farm colonies, the establishment of suitable industries in favoring localities and the like. But I am firmly convinced that success will come only when a helping hand—and a generous one—is held out to convalescent patients at their homes; for with nostalgia constantly exerting its powerful effects the best-laid plans of men will succumb. Wherever the interests of man clash with his happiness the former will have a hard time of it. The city-bred or born do not bear transplantation to the country with that equanimity which the movement "back to the soil"—principally confined to those who are well off and who are taking it up as a relief from the social grind—would lead the superficial observer to believe. And tuberculous people are not physically equipped for the stern struggle with nature which making a living from husbandry entails. The many gardens of Eden flaunted by real estate speculators, in the land of perpetual summer, are far away from home. And it will also be found that no miracles are possible there—hard work is here, as elsewhere in supposedly less favored climes, the touchstone for success in tilling the soil. Nor can one lose sight of the strain of taking up new occupations. Far better to minimize as far as possible the inherent evils of an occupation in which the patient has acquired proficiency than to try to train him in an unfamiliar task, no matter what the hygienic advantages of the latter may be. Far better to remodel the home life than break it up and move it away like a chattel. Just as we may lead a horse to the brook but not make him drink, so we may lead a man to the promised land and not have him take root. And if he does not take root, he withers, as we see often enough in the case of people who are trying to regain their health in far-off resorts. There are few cities in this country with inherently bad influences upon the convalescent—it is not the community or the "climate" but the conditions which are in the main at fault. These are not irremediable. The herculean task of ameliorating the living environment and the working conditions of the masses offers the only true solution. In this aspect the "home treatment" is the treatment *par excellence*—undertaken after the individual has taken a preparatory course in an approved sanatorium.

## THE INFLUENCE OF SODIUM CHLORIDE ON HYDROCHLORIC ACID SECRETION BY THE STOMACH.

By A. L. BENEDICT, A.M., M.D.,
BUFFALO.
CONSULTANT IN DIGESTIVE DISEASES, CITY AND COLUMBUS HOSPITALS; ATTENDANT, MERCY HOSPITAL; EDITOR BUFFALO MEDICAL JOURNAL.

It is rather late to reply to Dr. Floerscheim's negative conclusions as to the influence of a salty diet on hypochlorhydria and of a salt-free diet on hyperchlorhydria, published in the MEDICAL RECORD of June 8, 1912. Indeed, the writer has no intention of entering into a controversy but wishes to present merely a clinical statement of views regarding the general influence of chloride supply in the system to HCl secretion.

There can be no question but that the ultimate source of HCl in the gastric juice is chlorine in metallic combination. Elemental chlorine occurs only adventitiously and, if present in any appreciable amount, is toxic. Organic combinations of chlorine, except HCl in weak combination with proteins, may be similarly disposed of. The last is the result, not the cause of HCl secretion, although it may exist in considerable amount when the secretion of HCl is not sufficiently active to produce more than a trace of free HCl. The writer has often alluded to the production of HCl from neutral chlorides by sulphuric acid, as illustrating the power exerted by the oxyntic cells in their secretion of HCl. To deny that HCl is ultimately derived from neutral chlorides would virtually ascribe creative power to them. It is also stated on good authority that HBr and HI respectively are produced if corresponding salts replace chlorides in the ingesta.

Since HCl is formed from inorganic chlorides, it seems logical to assert that if the latter are absent in the ingesta, the HCl secretion will fail. But here, as in many other instances, certain practical qualifications must be borne in mind. First of all, the amount of chlorides passing through the system daily varies within wide limits. Many persons almost habitually pass 30 grams of chlorides, estimated as NaCl, through the body daily. No chemical erudition is required to establish this fact. Allowing for the air between granules, salt weighs just about a gram to each c.c. A tablespoonful, therefore, represents 15 to 20 grams. It is by no means rare to see persons actually eat a teaspoonful of salt at a meal—5 grams, three times a day—almost as much more is used per capita in cooking, by cooks who season highly, and there is also a smaller amount in all ordinary foodstuffs. Fifteen to 20 grams may also be checked up in the urine, not to mention the perspiration and feces. Nine to 10 grams may, however, be taken as the normal standard of daily intake and outgo of chlorides, estimated as sodium chloride. It is interesting to note that the Indians about Saratoga, according to contemporary statements, regarded the salt springs as the abode of devils, and ate no salt as such. There are of course, no data as to their secretion, but it is permissible to conclude that they were able to form an adequate secretion from the chlorides present in meat and vegetable foods. On the other hand, savages on the sea coast and near interior salt licks are said to have used these sources of salt.

To return to the therapeutic problem in the narrow sense, the writer has almost invariably found that on a diet as nearly salt-free as possible without special preparation of foods before they reach the cook, hyperchlorhydria abates. But it is not sufficient merely to interdict salt as a relish on the table. It must not be used in preparing the patient's food and he must not eat salty meats, salt butter, etc. With a diet salt-free, except for the natural content of ordinary insipid foods, hyperchlorhydria does abate in the great majority of instances although it tends to return if an ordinary salt-rich diet is taken, and there are instances in which either the patient does not tell the truth about his diet or in which there is so much superexcitability of the oxyntic cells that they produce an excess of HCl with the comparatively small amounts present in the body and assimilated, or rather appropriated, from ordinary foods. There is no *a priori* absurdity in this assumption. The human body (Moss) normally contains about 30 grams of sodium chloride, and its ability to hang on to chlorides to such a degree that silver nitrate will scarcely cause a precipitate in the urine, is a common phenomenon in certain diseases. As stated, whole tribes of Indians lived for years and probably for generations without salt as such. There is abundant analogy to show that the body can and does use various substances over and over again with almost no loss. On the other hand, there is evidence by analogy, as well as abundant clinical experience, to show that a person used to a liberal, *i.e.* wasteful ingestion of salt, usually has the HCl secretion diminished if he is suddenly forced to economy in chlorides.

There is a prevalent notion that the secretion of HCl draws acid radicles from the blood so as to produce an alkaline tide in the urine. The writer has shown that this idea is quite fallacious and anyone can adduce his own evidence by titration of the urine. It is true that after meals, the actual acidity of the urine usually falls somewhat, although alkalinity or even neutrality by phenolphthaiein is almost never reached, but this is due largely to the habitual ingestion of water, as such or in beverages, fruit, etc. But with allowance for urinary bulk, the actual acidity shows no such tide as has been taught from *a priori* logic; and for the most excellent reason that acid (gastric) digestion is almost immediately followed by absorption and by the beginning of alkaline (intestinal) digestion. Thus, there is a round and round production, combination, and absorption of either acid or alkaline constituents which by no means implies that there is a marked quantitative disturbance of equilibrium, necessitating elimination of an excess of either.

While there is an adage that "Figures do not lie," they may give even more false impressions than expert testimony. This is especially true of percentage and titration figures. Many men use the term hyperchlorhydria to apply to cases just beyond the physiological limits. A hyperchlorhydria of 50° of HCl and with a total acidity of 80°, is rather high. A total acidity for chyme of over 100° is very rarely exceeded and, with the standard test meal, we seldom deal with a larger accumulation than 250 c.c. at one time. But, for the sake of illustration, imagine a hyperchlorhydria representing 100° of HCl either free or loosely combined with protein, and of a bulk of 1,000 c.c. These figures, at least in their combined result, must represent pretty nearly the limit of hyperchlorhydria. The writer has seen a few cases of ischochymia with over 1,000 c.c. of chyme; a few cases with a total acidity of over 100°; none in which free HCl reached 100 or in which total free and combined HCl reached 100. In the hypothetical case we have a liter of contents of decinormal strength, containing, by definition, 3.65 grams of HCl, or 3.55 grams of chlorine. This is about a tenth of the amount normally available in the body and an amount which can be maintained on an apparently salt-free diet. It is quite conceivable that under the stimulus of pepper or other spices, alcohol, heat, etc., locally, or under psychic stimulus or as the result of the underlying organic change of hyperchlorhydria, there may be an excess of acid production in the stomach, in spite of the most careful restriction of diet. When we bear in mind the fact that the term hyperchlorhydria is commonly used for one-tenth as much stomach contents and half (or even less) as much acid strength, the statement that hyperchlorhydria is not influenced by salt restriction is reduced to the very moderate one that the various reflexes or the inherent pathological change of hyperchlorhydria may bring 2 per cent. of the regularly available chlorine of the body, within the stomach, without there being an excess of chlorine available from ingesta.

Now, it is obvious that such a statement is not necessarily contradictory to the statement that, other things being equal, the gastric oxyntic cells will not so readily secrete HCl when the supply of chlorine is at its normal minimum as when it is in excess. Nor does the fact that hyperchlorhydria or rather hyperchlorhydric exacerbations may occur when the diet is restricted in salt militate against the general clinical experience that such restriction, when thorough, does tend to reduce such exacerbations. We must not forget that hyperchlorhydria is merely a symptomic term. It may occasionally represent a mere functional tendency, but in the ordinary case it refers to a definite disease, very likely an actual

numerical hyperplasia of oxyntic cells. The functional tendency is subject to almost absolute control, temporarily, by diet and other means and recurrences can be treated as satisfactorily as in most diseases. But the patient, even when his stomach contents are reduced to normal acidity, is no more free from the underlying disease for which we have no term except the one which alludes to the fulminations, than a diabetic is free from diabetes because, under diet, his urine is free from sugar.

Regarding the opposite statement of Dr. Floersheim, that hypochlorhydria cannot be relieved by a diet rich in salt, the writer, in a sense, more than agrees, although there is something to be said on the other side, with some qualifications. First of all, it has been established that ingesta containing an excess of salt, tend directly to diminish gastric secretion. Whether this is merely another way of saying that osmosis does not occur into a medium already higher in soluble contents than the one on the other side of the membrane or whether there are more recondite reasons, need not be discussed here. Thus we cannot hope to benefit hypochlorhydria directly and immediately by giving salt.

It is not unreasonable to maintain that a system which has been starved in regard to salt or which, after years and generations of habitual salt excess, has been reduced to a diet containing only the normal proportion of salt in animal and vegetable tissues, may be benefited and may indirectly and gradually have its power of acid secretion restored by a judicious administration of salt and a selection of diet otherwise requiring and stimulating the secretion of HCl. The writer would claim such therapeutic value for salt only in the same general way as for any other condition depending on a deprivation, and with the same expectation of practical results, limited by other factors in accordance with general experience in therapeutics.

One very important limiting factor may be expressed in general terms as follows: The fact that one lives in a coal or natural gas region does not guarantee that his house will be warm; nor does a clay soil insure that a city will be built of brick. There is no more reason to expect a cure of hypochlorhydria from administering salt than of Addison's disease from administering adrenalin, or of leanness from administering fat. In many cases of hypochlorhydria, a definite atrophy of the gastric tubules exists. In others, there is a general failure of glandular functional capacity or a failure of innervation. The presence of an abundance of available raw material cannot, of course, insure its utilization. But just as there are cases of anemia in which the blood will recuperate its hemoglobin if iron is furnished, and cases of leanness in which the mere increase of fat or of food in general will afford relief, so there are occasional cases of hypochlorhydria in which the moderate, rational increase of salt, along with other appropriate dietetic and hygienic measures, will facilitate the reestablishment of an adequate HCl secretion.

228 Summer Street.

**Pulmonary Osteoarthropathy.**—V. Ball and H. Alamartine note that whenever the dog develops tuberculous lesions in the lung, there also develops a certain degree of hypertrophic osteoarthropathy. The latter lesion is the result of the action of the tuberculous toxins absorbed from the focus in the lung. It is concluded that a similar association between arthritic and pulmonary lesions occurs in human beings.—*Gazette des Hopitaux.*

## BIBLIOGRAPHIC STYLE IN MEDICAL LITERATURE.

By FRANK PLACE,

ASSISTANT IN THE LIBRARY OF THE NEW YORK ACADEMY OF MEDICINE.

The purpose of this paper is to call the attention of the man of medicine to the importance of the bibliography. In the sense in which I use it here "bibliography" means the list of references appended to the usual article in medical periodical literature.

Schools and colleges devote courses to composition of literary material. Libraries have been written on how to write. But who cares about the bibliography? Even the library schools lay little emphasis on the necessity of bibliographic instruction of authors. Practically a doctor begins to realize what constitutes a bibliography when he is preparing his first work of research for publication; but too often it does not get his interest or his care. By way of groundwork there are a few books and articles that the would-be author should read. First and foremost stands De Vinne's Correct Composition.[1] This is a really important work, reducing to a common denominator printer, publisher, and author. A French work by Thil[2] takes up the general subject of preparing a medical paper and of going through the literature for a given subject; while Allbutt[3] gives general observations on composition. Shorter, and bearing more specifically upon the present subject, are papers by L. N. Wilson,[4] Rolleston,[5] Fisher,[6] Eliot,[7] H. Wilson,[8] and the pamphlet, "Bibliographic Style,"[9] which should be on the reference shelf of every literary physician.

The librarian appreciates the bibliography more than any other person. To him come bibilographies many times a day, while the physician may not use a bibliography once in a month. The strange, not to say weird, references that the librarian is asked to locate lead him to think that many writers have no idea what the bibliography is for, that they don't care, or that they make up their bibliographies out of pure imagination. Therefore, as a librarian, I wish to state for the bibliography some of the reasons for its being, what it should be, and certain ideas which should obtain in its making. These reasons will, I hope, persuade my readers to give the bibliography its proper share of care, that it may most completely and correctly fulfil its purpose.

A majority of medical articles review, or depend largely upon, other writings. To indicate both to the writer and to the reader the sources from which this foundation comes is the province of the bibliography, or list of references. This list varies in its character with the nature of the writer and of the article which it accompanies. The article which gives merely an outline of a subject may have for its basis a text-book or a monograph, in which case the bibliography may be of the simplest. On the other hand, the worker who spends years on a special line of research and reads hundreds of articles will give to his report a long list of references, amounting perhaps to several pages, citing books, magazine articles, pamphlets, and the like.

From the writer's point of view, the bibliography is of importance. It retains in permanent form a record of the authorities he has used, to which he may need to refer at some future time. It shows how many or how few have held his opinion, or have differed. It may, too, be a select list, selected to

show the progress of his subject historically, or the work of men who have added their might or mite thereto. The reader, however, will want to know in addition to the points noted above: "How accurately has the author quoted his authorities?" or "Is he justified in drawing such a conclusion from this author?" or "What is So-and-So's method or technique?" The bibliography should be the key opening the way to the required information; it should afford a means of getting before the reader the right articles in the least time.

For purposes of defense and offense, therefore, each item of a bibliography should have certain qualities, lacking which it is by so much deficient and reduced in usefulness. These qualities are completeness and correctness. To be complete, the reference should tell: (1) Who wrote the article (the author). (2) What it is about (the title). (3) When it was published (the date). (4) Where it is to be found (if a periodical, its name and where in it).

Completeness and correctness are not synonymous. A citation may be complete but not correct. It frequently happens that an incorrect reference is worse than none at all; for much time is spent in searching literature for that which does not exist. Thus, "Niles, *Amer. Jour. Med. Sci.*, 1911, CXLI, 79," may through carelessness of author and typesetter become in print, "Miles, *Jour. Med.*, 1901, CXI, 179." Such accidents do happen. To condemn a reader to spend hours wading through the literary deluge in search of such an article partakes of the nature of a crime. The proposed aid becomes a serious obstacle, for it causes loss of time and unnecessary work, not for one person only but for many in many times and places. Even when found the paper may amount to nothing; but it has to be discovered before its uselessness becomes known. In the eyes of those to whom he has caused such loss of time and energy an author's work is not likely to rise in value.

Incompleteness is probably the most frequent fault in bibliographies. To measure up to the standard of completeness, the references should be as full of fact as are the items in the Index-Catalogue[10] and the Index Medicus.[11] These items may be grouped under two heads: monographs and periodical articles; or more closely, "independents" and "analyticals." By the first, the monograph or independent, we mean the book or pamphlet published by itself under its own title (not a reprint). The analytical is the article printed in a periodical, or the monograph which is printed in a "system" or "handbook."

A reference to an independent should include these details: (*a*) author's name with initials; (*b*) title of book; (*c*) edition, other than the first; (*d*) place of publication; (*e*) date of publication, or nearest ascertainable date when title-page reveals none; (*f*) the page, or pages, if a particular one is referred to. Here is such a reference: Campbell, F. R. The Language of Medicine. N. Y. 1888. p. 203-286.

A reference to an analytical should contain: (*a*) author's name with initials; (*b*) title of article; (*c*) title of periodical in which found (usually in abbreviated form); (*d*) place of publication, except when the city's name appears in the title; (*e*) date (year) of issue; (*f*) series and volume numbers; (*g*) pages covered by the article (p. 203-286), or the first page only (p. 203). In ordinary lists the latter form is quite sufficient. Such references are these:

Mosenthal, H. O. A Case of Pancreatic Diabetes Mellitus. *Arch. of Internal Med.*, Chic., 1912, IX, 339.

Coryllos, P. Adamantinome kystique du maxillaire inférieur. *Bull. et mém. de la Soc. anat. de Paris*, 1911, LXXXVI (sér. 6, XIII), 520.

Collins, J. Aphasia. *Modern Med.* (*Osler*). Phil. & N. Y., 1910, VII, 308.

In spite of what I have said as to the necessity of including certain data, an author must use his judgment or take expert advice in each reference as to what details should be indicated. This may seem paradoxical, but it is not. Let me illustrate, first with the page number. The American Druggist and Pharmaceutical Record uses two sets of page numbers. Each issue is paged by itself and also with the numbers that are its share in the complete volume. Thus, instead of indicating Walsh's article as 1911, LIX, 23 (p. 23 is only that page in the number of the issue for August 14), give it as 1911, LIX, 73. Again, take the reference of Coryllos above. Volume 13 alone might be mistaken for the 13th volume of the journal published in 1838. On the other hand, insufficient lettering may give only volume 13. In either case the reference has the right number indicated. Or it may be that there are other kinds of numbers to be indicated. That is, one must give the number of "année" or "Jahrgang." A good example of this occurs to me in the *Revue Neurologique*. In this journal tomes I-XVI coincide with années 1-16, but année 17 contains tomes XVII and XVIII and année 18 contains tomes XIX and XX. In a reference to a "Supplement," "Ergänzungsband," "Festband" and the like, indication of it must follow the volume number when its paging is separate from that of the volume it accompanies. And again, the individual monthly or separate issues may be the only thing to give, as in: Boss, S. Ueber Gonosan-Ersatz. *Berliner Klinik*, Okt. 1911, Jg. 23, Heft 280, 15-21. In fact, such variations in periodicals are legion.

Periodical titles and their abbreviations should be a matter of concern to the author. In most cases an abbreviated title is possible, and as a matter of economy is necessary, but it should never be allowed to degenerate into a cryptogram. The shortened form should indicate to the reader the words abbreviated, and, not less important, the language thereof. "Arch. Oph." rather should be "Arch. f. Ophthal." "Arch. d'ophthal," or "Arch. of Ophthal." The inclusion of the place of publication aids in the identification of the journal. Such an abbreviation as "A. f. O." may be used, as in von Noorden's book,[12] if a key to the titles accompanies the list. On the other hand, it is hardly wise to use the full titles, even with the words abbreviated, in the case of a few, usually German, periodicals. Instead of writing "Jahresb. ü. d. Leist. u. Fortsch. a. d. Geb. d. Neurol. u. Psychiat." one may use "Jahresb. Neurol u. Psychiat."

Do not translate titles. Do not clip them of important words. "Deutsche Zeitschrift für Chirurgie" is neither "Zeitschrift für Chirurgie," nor is it the "German Journal of Surgery" for purposes of reference. If the reader is unfamiliar with German, a translated title will lead him astray; if he does read that language he needs no translation.

Above all—and this is the law and the prophets—take no one's word for the accuracy of a ref-

erence. Ve ify each one yourself, even if it take some time. It probably will take time: out of each ten of your friend's references five will be incomplete and four incorrect. And finally when your own bibliography in proof comes from the printer —Doctor, this is for *you*—take your corrected proof and with no aid from the copy, look up in the magazines themselves each and every one of the items in your list. Better yet, let someone who is unfamiliar with your subject verify and correct your proof. Only then can you feel that your bibliography is fit to print.

To ask for all these details and for such care is not unreasonable. Let me show how in actual use these items are helpful; how one item acts as a check on a mistake in some other item. First, the author's name, to one acquainted with the workers in a particular field, affords a clue to the value of the paper. In event of error in other parts of the reference, the author's name is of great service in the search through indexes. Further, his initials identify him when we find several writers of the same name. The name is fixed, while the subject-entry of our article may be uncertain, or, in an unfamiliar language, unknown. The author's name is doubly important when, through lack of space, titles of articles are omitted. Swale Vincent[13] prints a long bibliography which is a good example of a most condensed form. He gives author, journal, date, volume, and page. While not always consistent he shows how sources may be located with a large number of entries in small space.

Suppose, again, that the author's name is wrongly printed and other data are insufficient or misprinted. Here the presence of the title gives a final chance to locate our elusive article by "sleuthing" through subject indexes and other bibliographies.

That an entry needs the title of the journal which contains the article seems self-evident; yet the frequency with which all reference to a journal is omitted seems to be reason enough for devoting this paragraph to some axiomatic statements: Put down on paper all the facts in the reference while it is before you; don't leave it to memory. Don't take anything for granted, and don't leave anything to the imagination: your readers are not mind readers.

The place of publication differentiates magazines of the same or similar titles, and in the case of independents (books) serves to identify editions and aids in the ordering and purchase of the same. This item is practically of the least importance and may be omitted without seriously impairing the usefulness of a bibliography.

Of most importance are the date, volume number and page number. I give these three together because they are interdependent and each acts as a check on a mistake in one of the others. I will show how, lacking one of these items, the reference is defective and may entail considerable delay in discovering the article cited. Take this reference: "Lancet, Lond. II, 359." Inasmuch as each year's issues of this journal since 1844 have been published as two separate volumes, 1 and 2, this reference may be in any one of sixty-eight volumes. The date at once fixes the volume: "Lancet, Lond., 1909, II, 359." Suppose now we have only the date: "Arch. f. path. Anat., Berlin, 1882." In this case we have to look through four volumes, and in each one not an index but two pages of "Inhalt." As this "Inhalt" is almost solid print with no catchwords, change in type or conspicuous position for items, the time consumed is considerable. Even "1882, XC" leaves us with two pages of reading, but "1882, XC, 549" enables one to put his finger on the volume and on the article itself in 10 seconds. In referring to journals in several series, an entry which gives the various volume numbers often aids by corresponding to the various ways in which such journals are bound and labeled, thus: "C. r. . . . Soc. de biol., Paris, 1886, XXXVIII (Sér. 8, III), 21."

There is scarcely a case in which either the year or volume number cannot be found in the journal from which you are making a citation. I will not say *no* case, for the ways of publishers are sometimes past finding out. Such a thing can be. For this reason, too, let no man say unto himself, "What does the lack of a page number signify? Let 'em look it up in the index." And alas! what an index it may be! The index in the volume referred to may be missing. It may never have been published. If present, it may be as weird as that of the Dental Review, in six or eight alphabets, and with entries like this under T: "The use of a normal salt solution." It may be only a table of contents set up "solid"; or the index may be in Volume 2 which is not yet completed.

As good an example as one is likely to find of a carefully made, consistent bibliography is that appended to a recent work of Harvey Cushing.[14] It is worthy of emulation by every medical author.

Having decided on the form of the entries in his bibliography, the author should have constantly before him the typical entry which shall be his guide. That is, if he has decided to give titles of articles in his references, let him use titles consistently in every citation. If he uses Roman letters for his volume numbers, he should do so in every case. If he capitalizes important words in one entry, let him do so in all. If he begins German nouns with small letters, he should not capitalize the English nouns and adjectives. If he follows German usage in capitalizing German words, let him follow French usage in the French words. Famulener's[15] and Cushing's[14] bibliographies are examples of consistency, though they differ from each other in style.

Having considered its parts, let us look at the bibliography as a whole. The question here is of arrangement. Several methods are followed, of which I will speak of four. One way is to enclose in parentheses in the text immediately following the author's name the reference to the book or article. "We are indebted to Schloss (*Amer. Jour. Dis. of Children*, Chic., 1912, III, 341)." This system is not frequently followed. Another method is to use a superior figure or character immediately after the mention of the author's name, or allusion to his work, with the character repeated at the foot of the page with the bibliographic reference. This mixes the ordinary footnotes with the bibliography, but is very widely used; as for instance, in the *American Journal of the Medical Sciences*. A third system, to my mind the most useful, especially for longer bibliographies, is the use of figures as noted above, but running in consecutive order to the end of the article, with the references collected at the end, in column form, as in the MEDICAL RECORD, or less clearly but more compactly, in solid type, as in the *New York Medical Journal*. A variation of this arrangement is to arrange the references in the alphabetical order of the author's names, number them in that order and then assign the numbers to their respective posi-

tions in the text. This is the method employed in Cushing's[14] bibliography. Still another method is to omit figures in the text and arrange entries of the bibliography alphabetically. This is confusing in the case of several entries by the same author, but is the form employed in the dissertations of the "Faculté de Médecine de Paris." In any event, the author will do well to submit his manuscript to an editor, or a bibliographic expert, before sending it to the publisher; or at least, to take as an example, a well rounded, careful and consistent bibliography already published. As a guide, the pamphlet "Bibliographic Style,"[9] already referred to, will be a valuable aid.

When one surveys the far horizon of the field of medical literature, he can see the value and necessity of definitiveness, of accuracy and completeness in references. Strangely enough, though, writers who have been tried by the mistakes in the work of others do no better themselves. I have in mind one who, after several evenings' work in finding his authorities from slipshod citations, published in his own bibliography this item. "Cent. f. Chir. Beilage, p. 37." Only this and nothing more. Another published a short list containing these: "Bost. M. & S. J." and "Hagner, Oct. 13, 1906." What is the purpose of such references? I pause for a reply. It is to laugh. But this is not so comic as it is tragic. An hour, or three, may not be such a great matter in time lost if it is only for one man. It is tragic in that many men in many times in many places all will lose that much, if they use such bibliographic blunders. To the librarian who handles such material every day, the bibliography assumes a real importance. At times he is led to believe that many writers look on correctness of reference as a countryman looked on the giraffe when he said, "There ain't no such animal."

That bibliographic style is open to improvement seems plain. Three channels are open through which this improvement can and should proceed: First, through a cooperative policy among medical journals and publishers in insisting on certain bibliographic standards; second, through the cooperation with them of medical libraries; and, third, through literary and bibliographic courses in medical schools. Certain, or uncertain, steps are being taken in this direction, but they lack coordination.

I shall not be surprised to find mistakes in spelling, grammar, and style, and even "rong references" in my own paper. I shall at least have tried to show what right references are; though, in this sketchy paper, I have not said the half of what I would like to, nor is what I have said half emphatic enough. I hope I have done something to put the bibliography on a footing of its own, to give it half a chance. As long as man is human mistakes will occur. The personal equation, human nature, the imp of the perverse, all take a hand in making the wrong appear right. Of that I cannot complain. What I do ask for is an *attempt* at completeness, an *attempt* at correctness and consistency in bibliographic style.

**Posthemorrhagic Anemia.**—L. S. Milne states that in rabbits and cats in which a hemorrhagic anemia has been produced, the hemoglobin is regenerated much more slowly than the red corpuscles, but the index, relative to the red corpuscles, never rises above one. The resistance of the corpuscles is not increased. In erythrocytes developing in the bone marrow, the nucleus of the erythroblasts seems to lose its chromatin, but is apparently not extruded. Punctate basophilia of the erythrocytes is a common feature and seems to result from a diffusion of nuclear chromatin through the cell. Extramedullary myeloid metaplasia is generally slight, but in moderately severe and long continued anemia from bleeding it may be very extensive. Lipemia usually occurs when the blood is reduced below a certain limit. The greater part of the fat in the serum can be extracted with ether and is stained by osmic acid. Extensive fatty infiltration of the organs may occur and also widespread necrosis in the central parts of the liver lobules. Pigmentation of the internal organs is usually only slight, but may be considerable, particularly in spleen. Although there are minor differences, all the essential features of anemia produced by toxins can be reproduced by hemorrhage.—*Journal of Experimental Medicine.*

**Lipoid Metabolism in Developing Chick.**—F. M. Hanes states that the liver of the embryo chick during the first two weeks of development contains an abundance of isotropic fatty globules which represent a mixture of lipoids in which phosphorized fats predominate. During the third week of incubation the fatty globules in the liver change their physical and chemical characters. They become anisotropic and exhibit the reactions and properties of esters of cholesterol. The phosphorized fats gradually disappear from the liver during the third week. The phosphoric acid utilized by the embryo chick in calcification is derived from phosphorized fats. It is suggested that the phosphorized fats are split in the liver, the glycerophosphoric acid portion being liberated for calcification, while the free fatty acids are esterfied by cholesterol. A review of chemical analyses of aortic atherosclerosis and calcification, and a comparison of the conditions in atherosclerosis with those of the developing chick liver, suggest that pathological calcification results from a splitting *in situ* of phosphorized fats with the subsequent formation of calcium salts, as suggested by Baldauf.—*Journal of Experimental Medicine.*

New York, January 25, 1913.

## THE NATIONALIZATION OF QUARANTINE.

EARLY in January two documents dealing with the proposition to place the Quarantine Station at the Port of New York under Federal control were made public. One of these documents was a report of the Public Health, Hospital, and Budget Committee of the New York Academy of Medicine, urging that the Quarantine Station at this port be transferred to the U. S. Public Health Service. The other document was the report to the State Legislature of Dr. Joseph J. O'Connell, for the time being Health Officer of the Port, urging that the New York Quarantine Station remain under his supervision. While it may be admitted that the right is not always on the side of the majority, nevertheless, when the majority is composed of one thousand of the leading physicians of New York City, moved solely by consideration of the public weal and with no personal interests in the matter, and the minority consists of one man, and that one the incumbent of the office it is proposed to abolish, the presumption is that the majority this time is in the right.

The arguments advanced by the public health committee of the Academy are in brief as follows: Of the fifty ports in the United States where quarantine provisions exist, forty-seven have been placed under Federal control and only three are managed by local authorities. The reasons for the transfer of the quarantine regulations of these forty-eight ports from local to national control were: (1) If the United States is to be a responsible party to international agreement regarding quarantine regulations, it must have control and supervision over all the ports of the country. (2) Quarantine work is essentially scientific in its nature and can be carried on efficiently only if the tenure of office is independent of changes in administration and of politics. (3) The Public Health Service has a well trained staff of medical officers and is thoroughly equipped for efficient quarantine administration; its record in the past, moreover, is such as to insure confidence in its efficiency for the future. (4) From the point of view of convenience, uniformity of administration, and economy the arguments are all in favor of a national control of quarantine in all ports of the United States.

The arguments advanced by Dr. O'Connell are also in support of national control, though he apparently does not think so. He says, "It (New York State) cannot wisely delegate its powers to any other agency because the magnitude and the nature of the quarantine work in New York so condition the problem that its solution requires that the supervisory and executive powers in all their amplitude shall be united in one person, and that this person shall be in a position to guide his judgment by a first-hand knowledge of the situation with which he has to deal."

It is precisely because of the magnitude of the quarantine work in New York and because "the prosperity of the whole State would be radically affected by any serious damage done to the commerce of its principal city" that the control of this great machine should not rest in one person, subject to removal by death or at the command of a political boss. In the business world it would be accounted madness to vest the control of a great undertaking in one mortal man instead of in a continuing corporation of trained experts, any one of whom is competent to take the helm in an emergency. The long and efficient administration of Dr. Doty was in a sense a misfortune, for it gave rise to a feeling of security in the permanence of competent State control which only the scandalous "trial" of this able public servant could shake. It has now been seriously shaken, for it is as certain as death and taxes that by the time Dr. O'Connell has gained experience and has perhaps won the confidence of the community by the exhibition of efficiency in some emergency the whirligig of politics will send him back to private practice and will again expose the health and commerce of New York to the mercy of the inexperience and possible incompetency of a new political appointee.

Another cogent argument for national control is the request of Dr. O'Connell for nearly two million dollars to pay for a virtual renewal of the plants at the Quarantine Station and at the detention hospitals on Hoffman and Swinburne Islands, and of an increase in the annual payroll of about $35,000 for thirty-seven new medical officers and assistants. Incidentally the present Health Officer pays an unconscious tribute to the efficiency of his predecessor who was able to accomplish so much without the two million dollars worth of improvements and the thirty-five thousand dollars worth of assistants which Dr. O'Connell says are necessary to enable him to do the work properly. By turning over the control of its quarantine at this port to the Federal Government the State will be spared the present expense of administration which amounts to about $300,000 annually and will also avoid the necessity of an increase of this expense by $35,000 each year for salaries and the interest on the $2,000,000 asked for improvements.

This is, therefore, an opportune moment, in the interests of economy, to ask the Public Health Service to assume the stupendous task of guarding the city and State, and the nation as well, against imported disease. The Public Health Service has performed this task elsewhere to the satisfaction of the entire country; the New York quarantine administration has also done this at times, and in some notable instances it has failed miserably; whether it will fail again depends entirely upon the experience,

ability, and personal character of the incumbent for the time being. The present Health Officer of the Port has discharged his routine duties creditably, but he has not been tried by any serious emergency, and it is no disparagement to his ability to say we hope he never will be. The citizens of New York and of the United States would view such an emergency with greater equanimity were it met by the trained sanitarians of the Public Health Service. The time must surely come when the control of the quarantine at this and the other two ports will be transferred to the Federal Government, and no time is better for this necessary and inevitable transfer than the present.

## A PRACTICAL PLAN FOR THE CARE OF THE FEEBLE MINDED.

Amidst all the talk about the duty of the State to care for the feeble minded there is surprisingly little to be discerned that deals in anything except the most vague generalities. It is therefore peculiarly refreshing to run across some definite plan, which is designed to meet the exigencies of the case as they exist at present, and which does not presuppose the existence of a perfectly organized, ideal political state.

In *The Training School* for November and December, 1912, Prof. E. R. Johnstone has outlined a plan whereby the feeble minded of the State of New Jersey can be properly cared for at the least expense compatible with good management. He proposes (1) that all feeble-minded children under the age of puberty, should be sent to the special classes in the public schools. This is in keeping with the idea that until the child becomes sexually or otherwise dangerous to the community he can safely be left at large and the parents can bear the expense of housing, clothing, and feeding during these years. (2) In the large cities of the State, which Johnstone enumerates but which it is unnecessary for us to mention here, he suggests that there be founded special municipal institutions for the feeble minded between the ages of 12 and 20, children from the special classes to be advanced to the institutions at the proper age. Here the expense must be borne by the municipality, the parents contributing what they are able and the State assisting, as it does now in the county care of the insane. The feeble minded of this group from the rural districts and smaller towns can be looked after at the Training School at Vineland. (3) Those who are twenty-one years or over can be cared for by the State at the custodial institutions already established at Skilman and Vineland, and the transfers should be made directly from the institutions for children to the State's institutions for adults. (4) Finally all the purely idiotic cases, that is, those whose personal habits are unclean and who need special care and attention, should be sent either to one of the above-mentioned institutions for adults or to the county almshouses.

This plan, as outlined by Prof. Johnstone as feasible for the State of New Jersey, would certainly be equally so for any other State which has already made a start in the care of its feeble minded. It combines the already existing private and public institutions in one general scheme which has for its ultimate aim the elimination of the defective strains. It is easy to see how the cost of such a plan would be very great at first, but as the years go on, the expense would rapidly grow less, because the death rate would naturally tend to eliminate the already existing supply of the feeble minded, and the plan of segregation, after the age of puberty, would tend to diminish very materially the birth rate of this unfortunate class.

## THE MODERN ASPECT OF DIABETES.

A lucid explanation of the complicated mechanism underlying the production of diabetes mellitus is presented by C. von Noorden in the *American Journal of the Medical Sciences,* January, 1913. The maintenance of the sugar content of the blood is one of the most important functions of the liver, which stores up the excess of ingested carbohydrate in the form of glycogen, and then converts this into sugar in response to the demands of the tissues. But the liver is not independent with respect to maintaining the balance between the supply and demand of sugar. The liver is under the control of two organs which act as antagonists. These organs are the pancreas and the suprarenal gland system. The pancreas through an internal secretion exerts a retarding influence upon the sugar production of the liver. Diminished activity of the pancreas, which is not always accompanied by anatomical changes in this organ, is the cause of a large number of cases of diabetes. The suprarenal gland system stimulates to a high degree the sugar-producing function of the liver. The glycolytic mechanism of the liver is kept normally in a state of equilibrium through the antagonistic action of the pancreas and suprarenal glands. The latter are directly under the control of the nervous system, as evidenced in the glycosuria resulting from puncture of the fourth ventricle. The pancreas is likewise influenced from without, its action upon the liver being inhibited by the internal secretion of the thyroid.

The fact is emphasized that the underlying pathological causes in diabetes may be found in several places, and that these causes are of unequal importance. There may be primary disease of the liver itself, but this really plays a subordinate rôle. There may be an affection of the suprarenal glands or of the nervous mechanism controlling them. This is the case in the neurogenous and toxogenous glycosurias. The most important cause of human diabetes is an organic or functional disease of the pancreas, or less frequently, some impairment of this organ through influences reaching it from the thyroid, parathyroids, and hypophysis.

Of eminent clinical importance is the recognition of diabetes as a complicated disease in which many organs are concerned, and in which the anatomical and physiological disturbances are not the same in different cases. Of fundamental importance in all cases of diabetes is the enormous irritability of the sugar-forming apparatus of the liver. The liver is excited to an increased sugar production by a slight excess of carbohydrate or even of protein in the diet; by excessive muscular work or

acute febrile attacks; by psychic and other nervous traumata; and by injections of adrenalin or thyroid feeding.

The main indication for treatment is to subdue the extreme excitability of the mechanism that is concerned in the metabolism of sugar. This indication is met by guarding the patient against the ill effects of physical and mental strain and by adopting the necessary measures in the restriction of diet. Frequent urinary examinations are indispensable in enabling one to regulate properly the diet of the diabetic.

### Pancreatic Concretions and the Pancreatic Syndrome.

That pancreatic concretions may obstruct the canal of Wirsung and produce well marked pressure phenomena without causing much shortage of external secretion may be due at time to slow growth and adjustment, such as the wearing of a thin groove in the stone. If the latter are not arrested permanently, the rapidity of their passage before the attainment of an obstructive degree of size would also account for the partial maintenance of the external secretion. At a recent meeting of the Royal Imperial Society of Physicians of Vienna (*Münchener medizinische Wochenschrift,* December 17) Glaessner exhibited two small pancreatic calculi, pea sized, and bearing a general resemblance to oxalic acid calculi. These were expelled spontaneously in the feces. There had been a history of repeated attacks of colic with eventually icterus and enlargement of both liver and spleen. There were marked salivation, achylia gastrica, alimentary glycosuria, and choluria. The patient had become cachectic. The feces showed muscle fibers and muscle nuclei but there was no special symptom whatever of pancreas failure. The diagnosis was chronic pancreatitis, pancreatic lithiasis, and incidental compression of the common duct which caused the addition of the liver syndrome. The patient received an oil cure followed by a Carlsbad cure and made a complete recovery. This case bears out the generalization sometimes seen in literature that even in the severest case of organic disease of the pancreas, the so-called syndrome of pancreatic insufficiency may be entirely wanting.

### Dust in Cities.

Among the annoyances to which city dwellers are subject, the dust nuisance is conspicuous. Under certain conditions also dust is a distinct menace to health, although it has been stated recently, and probably with a good deal of truth, that the dangers from dust have been considerably exaggerated. Outside dust, as a rule, does not contain hurtful germs, or rathes germs in so active a state as to be agents in conveying infection. Still, dust both outside and inside a house possesses various potentialities for harm. It can and sometimes does spread infection and in the ordinary way it irritates the respiratory organs and may be the exciting cause of several latent complaints of the breathing apparatus. In a few words, it may be stated with emphasis that the less dust is evident in cities the better will it be for the welfare of the inhabitants. Although, then, it is universally allowed that dust in cities is both a nuisance and a menace to health, there are but few places in which adequate and effective measures have been taken to cope with the evil. Discussion is rife and so is the dust. In rooms the custom of "dusting" merely sets in motion some of the dust and wafts it from one piece of furniture to another. In public halls, theaters, music rooms, and so on, ventilators move dust more or less laden with microbes and blow them into the noses and throats of those present. In short, no energy has been exhibited in fighting an obvious enemy to health and comfort. The means by which the inconveniences and dangers of dust may be abated are well known and need not be rehearsed here, the object in calling attention to the matter being merely to endeavor to arouse interest in a question which assuredly needs thorough ventilation in the medical and lay press.

### Advances in Paresis Therapy.

The discovery that nothing whatever is to be expected from the salvarsan therapy of paresis, which indeed is often aggravated thereby, coincides well in point of time with reports of the increasing efficacy of the pyretogenous substances tuberculin and nuclein in the early stages of the disease. Pilcz finds no less than 60 per cent. of improvement from tuberculin, and in private practice the percentage should be notably higher. But along with these results there appears a doubt as to the rationale of the action of the two substances. The fact that both of them are known to cause leucocytosis has influenced O. Fischer of Prague (*Berliner klinische Wochenschrift,* December 16) to employ other substances which are known to be leucocytogenous. It is, however, very probable that the pyrotogenous component is not inert and must for the present be retained. It was found that a combination of nuclein and mercury produced a high degree of leucocytosis and thus far it seems to give good results in practice. Chaulmoogra oil is also to be tried, and radium which also produces leucocytosis. The author expects to combine in the future antiluetic drugs with nuclein and other leucocytogenous substances. As he does not mention tuberculin in his summing up he apparently feels that we may be able to dispense with it ultimately despite its present efficacy.

## News of the Week.

**Philippine Medical Service.**—The United States Civil Service Commission announces for February 17 a competitive examination open to men only, for the purpose of filling a vacancy in the position of Chief of the Department of Medicine, Philippine General Hospital, Manila, at a salary of $4,000 per annum. The hospital has a capacity of 350 beds, and an excellent equipment, and is in close touch with the Bureau of Science with its fine research laboratories. Applicants for the examination must be citizens of the United States between the ages of twenty-eight and forty, and graduates in medicine. Permission to submit certificates is given by the United States Civil Service Commission, Washington, D. C., and application should be made at once for Form B. I. A. 2.

**State Civil Service.**—The New York State Civil Service Commission will hold an examination on February 15 for the purpose of filling the position of assistant superintendent of nurses, Craig Colony for Epileptics, Sonyea, at a salary of $900 and maintenance, this postition being open to women only;

and on the same day an examination for the position of physician at the Cohoes Jail, Albany County, at a salary of $300. Application blanks must be filed on or before February 7, and full particulars may be obtained from the State Civil Service Commission, Albany, N. Y.

**Army Dental Corps.**—The Surgeon-General of the United States Army announces that examinations for the appointment of Acting Dental Surgeons will be held at various places on April 7, 1913. The essential requirements are that the applicant be a citizen of the United States, between twenty-one and twenty-seven years of age, a graduate of a legally authorized dental school, and of good moral character and habits. Acting dental surgeons are employed under a three years' contract at the rate of $150 a month, and at the end of this time, if qualified, are promoted to the grade of dental surgeon. Fuller details may be obtained by addressing the "Surgeon General, United States Army, Washington," it being necessary that all applications be filed at least two weeks before the date set for the examination.

**New Cocaine Bill.**—The present law governing the sale of cocaine in New York having proved ineffectual in putting an end to the traffic, another bill has been drafted and will be shortly introduced in the State Legislature. The new bill makes the sale of the drug by an unauthorized person a felony, and the mere possession of it a misdemeanor, and provides that a druggist shall not have more than five ounces of the drug in his store at any one time, that a record of every sale shall be kept, that the drug shall be sold only in a solution or ointment not over one ounce and containing not over four per cent. of cocaine, and that the druggist shall keep each prescription and not refill it. The bill also provides that doctors, dentists, and veterinarians shall not have more than one ounce of cocaine in their possession at any one time, and shall keep a complete record of the disposal of the drug. Failure to abide by these sections is made a misdemeanor. The bill also seeks to regulate the sale of the drug by wholesalers in large quantities, complete records of such sales being required.

**Goats as Sanitarians.**—Fort Washington on the Potomac River having been condemned as unhealthful because of the dense growth of brush and the consequent breeding of mosquitos and flies, the War Department has decided to make use of goats as sanitary agents to clear up the premises and make them fit for human habitation.

**To Honor Professor Chiari.**—An informal celebration in honor of Prof. Chiari's sixtieth birthday will be held by his pupils on February 1, 1913, at the Clinic for Diseases of the Nose and Throat, Vienna.

**City Death Rate.**—During the week ending January 11, there were in New York a total of 1,512 deaths, as compared with 1,455 during the same week of last year. The death rate for the first two weeks of the year was 14.86 per thousand, while for the first two weeks of 1912 it was 14.42. There was, however, a decrease in the number of deaths of children under one year of age.

**Hospital Dedicated.**—The new building at the Lutheran Hospital, East New York, which has been erected at a cost of $20,000, was dedicated on January 19 with appropriate ceremonies.

**Deaths in the State.**—During the month of November, 1912, the deaths in New York State totaled 10,352, of which 804 were due to violence. In comparison with the same month last year, there was a decrease in the number of deaths due to tuberculosis, pneumonia, and typhoid fever, while the deaths from diphtheria, scarlet fever, and measles were slightly increased.

**Ambulance Smash-Up.**—An automobile ambulance of the Williamsburg Hospital, Brooklyn, was struck by another automobile at the corner of Broadway and Penn street, and both cars were badly damaged, while the occupants were bruised and shaken.

**Scarlet Fever Epidemic.**—Twelve students of the Massachusetts Agricultural College at Amherst, Mass., are ill with scarlet fever and quarantined in one of the fraternity houses, and the faculty has cancelled all arrangements for athletic games, dances, etc.

**Gifts to Charities.**—By the will of the late Miss Dessie Greer of New York, Mt. Sinai Hospital will receive $10,000 and the New York and Roosevelt Hospitals each $5,000, the bequest in every case being subject to the life interest of another person.

By the will of the late Miss Kate Clevenger of Lower Merion, Penn., the Bryn Mawr Hospital receives a bequest of $5,000 for the establishment of a free bed in the children's ward in memory of her brother, William H. Clevenger, and a further bequest of $5,000 for the establishment of a free bed in memory of her parents.

**Cerebrospinal Meningitis Spreading.**—According to the Public Health Reports of January 17 cerebrospinal meningitis has become epidemic in certain localities in Arkansas, Tennessee, and the southern part of Illinois. In Arkansas 25 cases, with 17 deaths, were reported at Lepanto, Poinsett County, during December and the first six days of January, and a few sporadic cases have been notified in other parts of the state. In Tennessee there were 108 cases, with 47 deaths, reported in Dyer County to January 13. In Lake County there were 13 cases, with 9 deaths, to January 13. In Carroll County there were four cases during the two weeks ended January 11, with sporadic cases elsewhere in the state. There were 13 counties in the state in which one or more cases were reported during the month ended January 14. In southern Illinois there were 11 cases, with 7 deaths, reported at Dale, in Alexander County, to January 10. Cases have also been reported at Cairo. Considerable agitation has arisen in connection with the appearance of the disease, and certain communities have established quarantine against other communities.

**Sterilization Urged.**—In his third biennial message to the Utah State Legislature on January 14, Governor Spry recommended the passage of an act requiring the sterilization of the hopelessly insane and of criminals convicted of certain statutory crimes.

**Antivivisection Again.**—The legislative controversy in New York on the use of animals in medical research was reopened on January 14 by the introduction into the Senate of a bill authorizing the appointment by the Governor of a commission of five members to investigate experimentation on living animals and report to the next Legislature what changes are desirable to protect the animals from unnecessary suffering without unreasonably interfering with legitimate scientific research. The belief that unnecessary suffering is inflicted by medical research workers seems to die hard.

**New York Quarantine.**—In his annual report to the New York State Legislature, Dr. Joseph J. O'Connell, Health Officer of the Port of New York, asks for what is practically a renewal of the plant at Quarantine and on Hoffman and Swinburne Islands. He also asks for additions to the working force which would mean an annual increase in the payroll of $35,000 to $40,000. In all the increased allowances requested amount to nearly $2,000,000. Dr. O'Connell opposes the plan of placing the port under Federal control, which he considers fraught with danger to the commerce of the city and consequently of the State. The report states that during the year ending September 30, 1912, 4,175 steamships and 710 sailing vessels were boarded by the officers of the department, and that these vessels carried crews amounting to 473,485, and 162,801 first class, 194,506 second class and 677,660 steerage passengers. In all, 6,304 persons were removed from these vessels for observation or detention, and on Swinburne Island 192 persons were treated, with fourteen deaths, and on Hoffman Island 218 persons with seven deaths.

**Fines for Importing Disease.**—The House of Representatives on January 15 passed the Kindred bill imposing a fine of $200 on any transportation company which brings to the United States a person suffering from epilepsy, any form of mental disorder, or dangerous contagious disease.

**Virginia Registration Act.**—During its last session the State Legislature of Virginia passed a new medical law containing the provision that within one year from the passage of the act all licensed practitioners of medicine in the state should register their licenses to practise in the office of the clerk of the circuit or corporation court of the county or corporation in which they reside. The law was approved on March 13, 1912, and it therefore becomes necessary for every practitioner in Virginia to register with the court before March 13, 1913, the penalty for failure to do so being a fine of $50 to $500, and in case of flagrant violation, imprisonment not to exceed six months.

**Administration of Antitoxin by the Health Department Inspectors to Be Discontinued.**—Commissioner Lederle of the New York Board of Health announces that on and after February 1, 1913, the present system of free administration by inspectors of the Department of Health of diphtheria antitoxin and performance of intubation at the homes of the patients, at the request of attending physicians, will be discontinued. After that date, when it becomes necessary for the Department of Health to administer antitoxin or perform intubation in any case of diphtheria, the patient will be at once removed to one of the hospitals of the department for further observation and treatment. Diphtheria antitoxin may still be obtained, free of charge, by physicians from supply stations at drug stores for use where payment for the same by the patient would be a hardship.

**Personals.**—Col. William C. Gorgas, chief sanitary officer of the Canal Zone, in response to a summons from Washington sailed from Panama for the United States on January 14.

Dr. John R. Slattery of Boston, Mass., has been appointed superintendent in charge of St. Elizabeth's Hospital, Boston, and also associate physician in chief to the institution.

**Marriage and Health.**—Mr. Duhamel has introduced a bill in the New York State Senate to amend the domestic relations law, providing that, with every license to marry, each party to the ceremony must present a certificate from a doctor of medicine duly authorized to practise in this state showing freedom from "disease due to immorality."

**British Physicians Yield to Lloyd George.**—On Saturday last, after a determined fight in behalf of the medical profession, the Council of the British Medical Association decided by a vote of 115 to 35 to release all members from the pledge they had given not to serve under the National Insurance act. The resolution releasing the members from this pledge followed a preamble "recognizing the force of present circumstances and consulting the best interests of the Association and the unity of the profession."

**Medical Society of the Missouri Valley.**—The spring meeting of this society will be held at the Coates House, Kansas City, on March 20, 21, and 22, the last day being devoted entirely to clinics in the various hospitals. The Jackson County Medical Society will be the host, and a symposium on cancer, a dinner at the Coates House, and an address by Surgeon-General Blue will be features of the first day.

**Medical Society Elections.**—Hartford (Conn.) Medical Society: Annual meeting at Hartford on January 6. Officers elected: *President,* Dr. Charles D. Alton; *Vice-President,* Dr. Everett J. McKnight; *Secretary,* Dr. John Carter Rowley; *Treasurer,* Dr. Philip D. Bunce.

Clay County (Ind.) Medical Society: Annual meeting at Brazil on December 19. Officers elected: *President,* Dr. Harold Pierce, Cleveland; *Vice-President,* Dr. Lewis L. Williams, Brazil; *Secretary,* Dr. Harry Elliott, Brazil.

Reno County (Kan.) Medical Society: Annual meeting at Hutchinson on December 27. Officers elected: *President,* Dr. H. H. Heylmun; *Vice-President,* Dr. Charles L. McKittrick; *Secretary-Treasurer,* Dr. W. F. Schoor, all of Hutchinson.

Jefferson County (Ky.) Medical Society: Annual meeting at Louisville on December 23. Officers elected: *President,* Dr. Dunning S. Wilson; *Vice-Presidents,* Dr. Harry J. Phillips and Dr. Guy P. Grigsby; *Treasurer,* Dr. E. L. Henderson, all of Louisville.

McCracken County (Ky.) Medical Society: Annual meeting at Paducah on December 18. Officers elected: *President,* Dr. H. G. Reynolds; *Vice-President,* Dr. C. E. Kidd; *Treasurer,* Dr. H. P. Linn; *Secretary,* Dr. E. B. Willingham.

Cumberland County (Me.) Medical Society: Annual meeting at Portland on December 20. Officers elected: *President,* Dr. E. E. Holt, Portland; *Vice-President,* Dr. J. L. Bennett, Bridgton; *Secretary,* Dr. Philip P. Thompson, Portland; *Treasurer,* Dr. R. B. Moore, Portland.

Sagadahoc County (Me.) Medical Society: Annual meeting on December 18. Officers elected: *President,* Dr. Isaac C. Irish, Bowdoinham; *Vice-President,* Dr. A. A. Stott, Woolwich; *Treasurer,* Dr. R. H. Donnell, Bath; *Secretary,* Dr. Robert C. Hannigan, Bath.

Knox County (Me.) Medical Society: Annual meeting at Camden. Officers elected: *President,* Dr. Frederick B. Adams, Rockland; *Vice-President,* Dr. E. B. Silsby, Rockland; *Secretary-Treasurer,* Dr. Horatio W. Frohock, South Thomaston.

Kennebec County (Me.) Medical Society: Annual meeting at Augusta on December 26. Officers elected: *President,* Dr. S. J. Beach; *Vice-*

*President,* Dr. Wellington Johnson; *Secretary,* Dr. Henry W. Miller; *Treasurer,* Dr. George R. Campbell, all of Augusta.

Hinds-Rankin Counties (Miss.) Medical Society: Organized at Jackson on December 18. Officers elected: *President,* Dr. R. S. Curry, Jackson; *Vice-Presidents,* Dr. T. M. Hall, Clinton, and Dr. J. E. Watson, Florence.

Missoula County (Mont.) Medical Society: Annual meeting at Missoula on December 28. Officers elected: *President,* Dr. H. B. Farnsworth; *Vice-President,* Dr. E. C. Anderson; *Secretary-Treasurer,* Dr. C. L. Bordeau, all of Missoula.

Galveston County (Tex.) Medical Society: Annual meeting at Galveston on January 3. Officers elected: *President,* Dr. W. F. Starley; *Vice-President,* Dr. W. P. Breath; *Secretary-Treasurer,* Dr. W. C. Fisher, Jr.

Caddo County (Okla.) Medical Society: Annual meeting at Anadarko on December 27. Officers elected: *President,* Dr. P. R. McClure, Fort Cobb; *Vice-President,* Dr. G. W. Westermeier, Anadarko; *Secretary-Treasurer,* Dr. C. R. Hume, Anadarko.

**Obituary Notes.**—Dr. Wolfred Nelson of New York, a graduate of McGill University and of the University of Bishop College, Faculty of Medicine, Montreal, in 1872, a non-resident Fellow of McGill University, a Fellow of the Royal Geographical Society of London, and a member of the British Medical Association, died in the Hudson Street Hospital from pneumonia on January 15, at the age of 66 years. Dr. Nelson was known as an expert on tropical medicine and climatology, having made extensive researches on these subjects in Cuba, Mexico, and Central and South America, and his work had been recognized in Spain by the bestowal of the Order of Queen Isabella the Catholic with the rank of Commander.

Dr. Orrin F. Harris of Norwich, Conn., a graduate of the College of Physicians and Surgeons, New York, in 1865, died at his home after a brief illness on January 4, aged 69 years.

Dr. Henry Woodward Jones of New York, a graduate of the Detroit College of Medicine, Michigan, in 1874, died at his home in White Plains from diabetes, on January 14, aged 65 years.

Dr. James F. Bothfeld of Newton, Mass., a graduate of the Boston University School of Medicine in 1888, formerly assistant superintendent of the Westboro Hospital, a member of the American Institute of Homeopathy and the Massachusetts Homeopathic Medical Society, and attending surgeon to the Newton Hospital, died on January 12, after a short illness, aged 47 years.

Dr. Raymond H. Pillow of Butler, Penn., a graduate of the Jefferson Medical College of Philadelphia in 1876, and a member of the Pennsylvania State and Butler County Medical Societies and the American Medical Association, died at his home on January 10, from secondary process incident to cerebral hemorrhage, aged 59 years.

Dr. Frank R. Higgins of Philadelphia, Penn., died at his home on January 9, aged 66 years.

Dr. William A. Grove of Galva, Ill., a member of the Illinois State and Piatt County Medical Societies, died at his home on January 9, after a long illness.

Dr. Paul E. Thibodaux of Montegut, La., a graduate of the Medical Department of the Tulane University of Louisiana, New Orleans, in 1892, died suddenly from apoplexy, on January 6.

## Correspondence.

### INFLATION OF STATISTICS.

To the Editor of the Medical Record:

Sir:—Permit me to add a few words in rebuttal to Dr. Mandlebaum's letter which appeared in your valuable journal on the 18th inst. I do not think he was quite fair to quote disconnected sentences of my paper in the endeavor to justify his failure to give me credit for the case. He admits that I recorded my cases under the caption of "Primary Splenohepatomegaly in Brother and Sister," in other words, that I was certain that the disease is primary in character, occurs in several members of a family, and is manifested principally by pronounced enlargement of the spleen and subsequent hypertrophy of the liver. Now, if Dr. Mandlebaum, before writing his letter, had taken the trouble to read his own recent paper on Splenomegaly and to compare the characteristics of the disease as he has found them to be with those briefly expressed in the caption of my paper of November 4, 1911, he certainly would have hesitated to assert that my cases were not diagnosed by me. I probably would have gone a step further to enlighten him and would have added the words "Gaucher type" with capital letters, were it not for the suggestion of no less an authority than Dr. A. Jacobi (whom I had the pleasure to consult on the last case) that "my cases were of the kind every author has lately been describing under a different name." Let me state also that the photographs of the children accompanying my paper were so beautifully reproduced in the Medical Record that Dr. M. S. Reuben and his associates immediately recognized the case. Furthermore, that after the doctor's article appeared, he apologized to me for not giving me credit for the case, explaining that the time was too brief (two months!) to have made the necessary correction in the manuscript or proof. I beg also to state that it was upon my solicitation, to please Dr. J. Wiener, that the parents consented to have their child operated upon, so that practically everyone connected with the case was fully aware of the fact that the case was mine, particularly since I had also the occasion for several years to treat his sister who died two years before.

### OXYGEN IN THE TOXEMIA OF PREGNANCY.

To the Editor of the Medical Record:

Sir:—In your issue of January 11, 1913, there appears an article by Dr. George P. Shears entitled "A New Method of Treating the Toxemia of Pregnancy." The method consists in the free use of oxygen by inhalation and subcutaneously, and he refers to this procedure as new and unknown either in Germany, France, or England. The injection of oxygen under the breasts in eclampsia is not altogether new and unknown. The method was given a fair trial some two years ago in the Wertheim Clinic, Vienna, and I believe also in some of the other German clinics. The results were not satisfactory. However, Professor Wertheim made use of the preparation on an altogether different principle.

About that time Professor Sellheim of Tübingen

announced his theory that eclampsia was due to a perverted action of the mammary gland and attempted to cure the condition by removal of the mammæ. He reported a case that he cured by an amputation of the breast. Wertheim wanted to give the method a trial, but did not want to resort to such radical treatment. His idea was to isolate the breast by interposing a cushion of oxygen between it and the rest of the body. We were not satisfied with the results.

Amputation of the breast for eclampsia has been ridiculed very much, and the method of injecting oxygen under the breasts has also fallen into disuse.

## ATMOSPHERIC DEVITALIZING INFLUENCES.

To the Editor of the Medical Record:

Sir:—A recent editorial article in the Medical Record drew attention to the claims, emanating from a British source, that high percentages of carbon dioxide in air are not deleterious to health. There is no question but that wide variations in moisture, heat, and movement in the air may be damaging to health, as they certainly are to conditions of bodily comfort. But what basis exists for the new idea that respired air may be practically innocuous as far as its $CO_2$ content is concerned? This new contention has been backed up by some experimentation which has shown that individuals may be confined in atmospheres containing unusual amounts of $CO_2$, and if the air breathed is kept cool and in motion no discomfort is experienced. The further argument is advanced that air at high altitudes may have a lesser proportion of oxygen per stated bulk than much breathed air in inclosed spaces, but is healthful. All this may be true, but such evidence does not warrant the conclusion that much breathed air may not be objectionable. Leaving aside the objections to such air that may be due to organic contaminations, living or dead, there is certainly an objection to breathing air that has an excess of $CO_2$ in it, because that gas has a devitalizing effect on living tissues. The argument has no value that claims no damage done if no discomfort is experienced. One might as well say that tobacco or alcohol has no damaging, devitalizing effects, yet we know that both of these compounds directly devitalize in proportion to their absorption into living tissues. Nicotine, next to hydrocyanic acid, is the most deadly poison known, yet it can be used for a long time without discomfort, and even with much pleasurable experience. Still it does devitalize, and indirectly and more or less ultimately, causes great physical damage to the race. In view of the lamentable lack of existence of general knowledge as to the influence of these as well as other devitalizers on health, it seems to be a matter to deplore that this new idea of no damage from $CO_2$ in air breathed should be advanced. Much publicity has been given to it as presented, and it may do great harm. Carbon dioxide is one of the poisons that is continually being manufactured in the body, which is continually being got rid of by the body. If the body does not get rid of it quickly enough, not only is discomfort experienced, but the death of the body ensues. That fact can be demonstrated very readily by a hard run in even a very cold wind. If the heart and lungs cannot act quickly enough the same result will be experienced. The idea that mountain air is healthful notwithstanding small percentages of oxygen in the air is a *non sequitur*. It may be healthful because it is pure and cool and dry; but as a matter of fact, for most individuals, and with other conditions equal, the greater the atmospheric pressure is, with consequent richness in oxygen, the greater is the vitalizing influence experienced by those who breathe such air. People who are under the influence of devitalizers live slowly and are more subject to other damaging influences that find their opportunity to attack tissues that are defective in vital activity. Those heating devices, such as the steam radiator and the regenerative hot-air furnace, while they save coal through the use in cycle of breathed air, are deadly devitalizers of those who habitually seek comfort through their use. It is rather strange that this new fallacious sanitary idea should have come to the world from England, the home of the open fire and fiercely uncomfortable ventilation. Nevertheless the idea is fallacious.

## OUR LONDON LETTER.

(From Our Regular Correspondent.)

INSURANCE DIFFICULTIES—MR. LLOYD GEORGE EXPLAINS AND DEFENDS ACT—LONDON MEETINGS—CHOLELITHIASIS—OBITUARY.

London, January 3, 1913.

All the week we have been flooded with statements, appeals and other documents about the Insurance Act. Besides the arrival of these by post, our newspapers have given us column on column every morning on the various features of the controversy that has arisen. The organs devoted to the government party have displayed little scruple in defending Mr. Lloyd George and openly boast that he has split the profession and will certainly triumph over it. It would be no easy task to enumerate and correct their misrepresentation of facts and their libelous attacks on the faculty are too scandalous to quote No doubt a number of men have agreed to serve under the Act, but they are so decided a minority that it is by no means certain that the panels can be filled, and many close observers expect to see the scheme collapse.

A very unpleasant controversy has been waged as to the obligation of the pledge which was signed, as you may remember, by 27,000 practitioners. It was a promise not to take service unless the "six cardinal points" of the B. M. A. were granted. When the government flatly refused, but gave way on some minor points, the association put forward an alternative policy. This has not been approved by all, and those who were willing to accept the revised terms broke away and formed new organizations which the B. M. A. calls "schismatic." These are begging us not to sell our freedom and become State servants. The association replies that not to keep the pledge is selling our honor. There can be no doubt that circumstances have changed. The B. M. A. says the revised terms of the government have changed, though one hardly sees in that a proof that their own policy has not. The "schismatics" say the B. M. A.'s policy has changed and a promise to stand by one cannot be made to include another. That there is great force in this is seen in the important step taken by six members of Council who have resigned their offices rather than be connected with the attempt to enforce pledges given for the original policy to carry out the alternative one. Another representative meet-

ing is called for the 17th, and certain newspapers consider this as preliminary of a submission to the government. It is nothing of the kind, but has been rendered incumbent on the executive by a requisition from some of the divisions who demand a decision as to the pledges. Meantime Mr. Lloyd George has written to a "schismatic organization" that doctors who go on the panels will be protected by the whole power of the government from boycott and intimidation if necessary.

Wednesday brought out a copy of the B. M. A. manifesto to the profession. It sets out fairly the objections to the Act, emphasizing that the profession would be placed under the control of working men who are not fitted by education or training to deal with questions likely to arise. Further, that the doctor is required to pay for on anesthetist, is allowed nothing for mileage, and there is no income limit because, as the chancellor has admitted, it would lead to loss of votes. How many doctors, says the manifesto, depend on small fees from patients just a little better off than members of their clubs, and may accordingly be ruined because these patients will be swept into the insurance net. For the success of the Act it is calculated that 10,000 doctors will be wanted; less than 8,000 would spell disaster. The conclusion drawn in the document is that the scheme of the association would be for the best interests of the insured persons.

On Tuesday London practitioners residing on the north side of the Thames met and conferred with the Insurance Committee. Much difference of opinion prevailed on several points among the representatives of the nineteen boroughs concerned. It was held, however, to be advisable to arrange for one local committee to be formed for the whole of London and a number were appointed to serve in conjunction with those to be chosen the next day for those practising south of the Thames—one or two for each borough, and in addition two qualified women were nominated. The South Londoners duly met, as arranged, and agreed substantially with their Northern colleagues. The result is therefore united action in London by those who accept service. It was announced that the time for joining the panel was extended until to-morrow—this after many denials that any delay would be permitted. This change is thought to indicate that there are not sufficient numbers available, but government organs pretend that the rush is such as to need checking. The medical committee for London being thus formed is to be consulted in regard to all questions affecting practitioners under the Act. The conference decided unanimously to work on the capitation system. At the meetings of both Northern and Southern residents the question was raised whether a man on the panels would be bound to attend patients of their neighborhoods who declined the service. Many declared they would not take such patients, and demanded the chairman's ruling, but he gave only indefinite answers, and after much pressing said the commissioners would be lenient in this matter. One who had put his name on the panel declared that he would certainly withdraw it if he were expected to steal his neighbors' patients. Some have prefixed to their signatures a condition that they are not to be asked to accept such patients. The chairman of the conference admitted that such a condition might be added. Government organs produce a sort of official report of these meetings, but it is very incorrect.

Yesterday the Chancellor of the Exchequer delivered the speech he had promised to give in explanation and defense of his Insurance Act as it affects the medical profession. Addressing the Advisory Committee, he boasted that his success was complete, for over 8,000 doctors had sent in their names for the panels, and in a day or two the 10,000 supposed to be requisite would be obtained. This may be correct, but when he went on to say that most, if not all, of the several areas in the country were thus filled, he was, as usual, misrepresenting the facts. There are districts where no one has agreed to serve, others where miles intervene between those who are willing. In the Isle of Wight not one is ready to serve. The Surrey Committee last night said that in three-quarters of the county the formation of a panel was not possible. Hertfordshire is as obdurate. In the great towns there is the same inequality of distribution; in Oldham and Birkenhead, *e.g.* only two practitioners have become candidates; in Barrow three; in Northampton 4, and so in many others, though changes may occur from day to day if the time be extended as suggested.

Mr. Lloyd George next propounded a reply to the objection to lay control and expressed surprise that it should have been urged, as payments by the State are always subject to it. He specially alluded to the question put by one and others as to what his own profession would think of such a scheme being proposed in their case. In answer he declared they never objected and proceeded to confuse the issues. As town clerks, or clerks of the peace, or to magistrates, he said the lawyers never objected to lay control of the funds out of which they were paid.

Of course not—neither do medical officers of health and other salaried officials. But this is not a parallel case. Let him offer six or seven shillings a year to his learned colleagues of the law, with the duty of furnishing a client with all the legal aid he might ask for during that year.

Mr. George complained that he had given deputations repeatedly to the B. M. A., but could not arrange a compromise, and at the last moment they had reversed their policy, trampling on their own constitution, without consultation with their constituents. Admitting they have done this, it is no justification of his own course, which in some respects he has had to admit is against the intention of parliament.

A number of other points were taken up in the Chancellor's long speech, and then he came to the pith of it all—what he would do if the panels could not be filled. He evinced a most determined attitude and threatened other arrangements. These were to send additional doctors into the districts and to provide a salaried service, with permission to practise among the families of the insured. This he saw would be ruinous to some individuals, but he was not to blame; he was sorry for them, and had tried to avert it, but they must put the blame on the shoulders of those who had so advised them. Government was pledged to supply medical benefit to the insured, and would do it; yes, pledged to the "approved societies," which is, he reckons, to the voters.

One other point must be noted. Free choice of doctor has been promised all along to the insured. Mr. Lloyd George "explained" this away as only applicable to very exceptional cases recommended by the local committee.

In the Section on Balneology (R. S. M.) a paper

by Dr. Bain, on Cholelithiasis, evoked some interesting experiences. He laid stress on obstinate dyspeptic symptoms as indications for examining the region of the liver. Tenderness on pressure over the gall-bladder invariably preceded the formation of calculi in it, and was no doubt due to its inflamed condition. The normal gall-bladder would dissolve any biliary calculus introduced into it under aseptic conditions. The treatment was to improve digestion, correct injurious habits, and direct suitable exercise. When digestion became nearly normal colalin and urotropin might be administered for several months. Dr. P. Lewis, presiding, remarked that these measures improved the resistance to microbic invasion. Dr. Solly argued that once the diagnosis established, the treatment should be surgical—the only curative measure—and he was supported by Mr. C. Forsyth, who said that now and then the escape of the stone into the bowel took place, but to postpone interference until complications arose was unfair to the patient and to the surgeon. Dr. Keay, who had himself suffered from the disease, thought it would often yield to treatment directed to the digestion, and only in rare cases was operation required. He had been treated at Carlsbad with success. Dr. Bain, in reply, said urotropin was excreted in the bile. He advocated a yearly course at a spa after operation, as that measure did not remove the causes. The surgeons as a rule did not see the mild cases, and their views therefore were based on observations in the advanced stages.

A week after the foregoing discussion Dr. Holland reported at the Liverpool Institute three recent cases of gallstone which he had detected by the *x*-rays. Their bulk was transparent, but they had a crust of lime salts which gave a shadow, and this differed from a calcareous gland and also from a renal calculus. He showed afterwards the three shadows on the screen.

The death was recorded on December 31 of Dr. H. Philpots of Birkenhead, an Aberdeen graduate with honors, 1877; Consulting Surgeon to Dartmoor Convict Prison, who held also other appointments.

Dr. A. C. Chalmers, formerly of Sheffield, has died at the advanced age of eighty-four years, having retired for many years. He took M.D., Edin., and the Surgeons' College there in 1848. At one time was surgeon to the Perth Infirmary.

Surgeon-Lt. Col. W. T. Colby, M.D., J.P. for North Yorkshire, died on December 22, aged eighty-five.

## Progress of Medical Science.

*January 9, 1913.*

1. Report of 110 Cases of Renal and Ureteral Calculi and of Ten Cases Simulating These Conditions, with Comments. F. S. Watson.
2. Some Results of Dispensary Work in the Control of Tuberculosis. C. Floyd.
3. The Sacrifice to Asklepios: A Mime of Herondas. R. M. Green.
4. The Treatment of Hypospadias. H. A. Lothrop.
5. A Case of Pellagra. W. H. Sherman.
6. Pellagra, with a Report of Cases. E. H. Cohoon and F. J. Farnell.

**1. Renal and Ureteral Calculi.**—F. S. Watson, in reviewing a series of 110 cases of renal and ureteral calculi, notes that he has found the following treatment to be most effective. In the medical treatment of renal colic the combined use of ether inhalations and moderate doses of morphine should be resorted to. Heat should be applied to the affected side, and an abundant supply of water should be administered. The patient should be kept on a liquid or milk diet. To aid in the expulsion of the calculus from the kidney the treatment far the most successful in the author's experience is: spirits of turpentine in 10 minim doses in gelatin capsules three times a day. The diet should consist of milk, each tumblerful diluted one-quarter part with Vals' water, the milk to be slightly warmed and drunk slowly. Fish and dry toast may be taken once daily. Patient is to rest recumbent during the regimen and to take occasional hot sitz baths. The treatment should last six days consecutively, then after a two days' interval it should be repeated once or twice, if necessary. After one month or six weeks of this treatment at most, if the stone has not passed, it should be removed by surgical operation. In every one of the author's cases in which the patients were freed from their calculi by medical treatment, cure was absolute and in twenty of these cases the patient's history was followed from three to twenty years subsequently. In but a very small number of these—six—was there any recurrence of the trouble. These patients got rid of their recurring calculi under the same treatment as was employed in the first instance. In seven of the cases treated medically there was failure to cause the calculus to pass. These patients were operated upon successfully later. In 87 per cent. of the author's cases thus treated, in which the calculus was small enough to pass through the ureter, it was spontaneously expelled, while the patients were under medical treatment.

**2. The Dispensary Treatment of Tuberculosis.**—C. Floyd states that statistics show that the dispensary has a well defined and valuable place in the control of pulmonary tuberculosis. Its work cannot be measured in the terms of "cases cured" as can that of the sanatorium, but its usefulness is almost entirely along the lines of diagnosis, isolation, and prevention. The conclusion would seem justified that in the absence of any specific remedy for pulmonary tuberculosis, its suppression will be brought about by the multiplication of those agencies at present working against it. Neither the sanatorium, the hospital, nor the dispensary alone can make much headway, but working together as one unit they will in time fully justify their existence.

**6. Pellagra.**—E. H. Cohoon and F. J. Farnell conclude from their study of this disease that there appear to be several factors standing out prominently. Fifteen out of the twenty-seven cases evinced absent knee jerks, eight gave distinct evidence of peripheral polyneuritis even to the extent of foot drop and muscular atrophy; five cases had diminished knee jerks. Secondly, as in low toxic conditions and infections there was observed a distinct change in the blood picture not unlike that seen by other observers, the differential blood count being one of a small mononucleosis. The cytological count in the spinal fluid although small, two to nine cells per c.mm., appeared to be of sufficient weight to indicate a chronic inflammatory process. The microscopic findings in the central nervous system were suggestive of a central neuritis, the nerve cells showing an infectious or febrile condition of a parenchymatous nature. If, on the one hand, pellagra is to be considered of a toxic or infectious etiology and showing central neuritic evidence; and on the other hand, is distinctly an afebrile condition of unknown bacteriology, it is possible, or even probable for pellagra to produce neuritic symptoms of central as well as of peripheral origin, such as has been seen in the clinical exposition of the author's cases.

7. Tuberculous Meningitis. S. Schaeffer.
8. Vanadium Selenium in Cancer. F. von Oefele.
9. The Auscultatory Method of Blood Pressure Readings. J. F. Prendergast.

1. **Pyloric Spasm and Pyloric Stenosis.**—H. Koplik classifies these cases as follows: (1) Pure spasm of the pylorus and the pyloric end of the stomach without any palpable pylorus, with peristalsis and explosive vomiting, loss of weight, and consequent inanition. The constipation present may be only a relative constipation, that is, some fecal matter passes, or there may be several movements, green and fluid in twenty-four hours, or of a brownish color, or the constipation may be absolute and on forced movement of the bowels, little or no fecal matter passes. (2) Pyloric spasm with relative and actual stenosis, with slight or marked thickening or hypertrophy of the tissues of the pylorus. Such cases give vomiting of an explosive type, coming on soon after birth, and continuing for some time with a palpable pylorus, at first, or subsequent to the onset of symptoms. The pylorus can be felt to harden under the finger at the time of greatest peristalsis of the stomach, and to soften after vomiting has occurred. There is constipation, complete at first, which after some duration of the disease mitigates, and fecal particles may appear in the stools. There is marked progressive atrophy and inanition. (3) Congenital hypertrophy of the pylorus so-called with stenosis. These cases, which are only relatively more marked in their symptomatology than the previous class, give exactly the same symptoms; there is the same spasm of the pylorus as an accompanying symptom, the pylorus can be felt just as in the previous class, the peristalsis is just the same, and the constipation is the same, only possibly more marked. In fact, clinically it is the same condition, only it may manifest itself in more aggravated forms than in the cases in which the hypertrophy and stenosis are not so marked. They are practically the same set of cases as in Class 2. When operated upon the cases in Class 3 may show considerably more enlargement and hardening of the pylorus than was evident before the operation. This has given rise to the presumption that these cases are a distinct entity apart from Class 2. The author believes that both of these sets of cases merge into each other and are pathologically the same, though clinically one seems a more aggravated condition than the other.

5. **Crotalin in the Treatment of Nervous Diseases.**—J. B. Woodruff points out that the exact therapeutic action of crotalin is not understood, but this drug probably acts as a stimulant to the central nervous system, as is well illustrated by its effect in nerve exhaustion. Spangler believes that it has a decided influence in revitalizing the functions of the various organs. Another apparent effect is its ability to block undue outside stimulation on the nerves of special sense. Possibly this is illustrated by cases of insomnia in which refreshing sleep is produced without any signs of narcotism. The drug is to be given by hypodermic injections. It is best to give the first two or three injections in the back of the arm and always to begin with a small dose, as 1/200 or 1/150 of a grain. Later the injections are better given in the back where they cause very little reaction. The injection should be given as a rule every five to seven days. In epilepsy the drug causes a diminution in the severity of the attacks. The intervals between attacks are lengthened. The mental activity of the patient is greatly improved. In cases of neuralgia and neuritis, including sciatica, lumbago, tics, coccygodynia, etc., a few injections of crotalin cure the case and often the first injection gives marked relief. In some cases of asthma the crotalin acts almost as a specific and has improved all cases in which it has been tried.

8. **Vanadium Selenium in Cancer.**—F. von Oefele believes that the basis of the selenium treatment is the chemical action of selenium as an oxidizer; especially in carcinoma selenium increases the oxidation of sulphur compounds. Selenium affects particularly the crypt cells of carcinoma. These cells become, by selenium treatment, colloidal. The parenchyma swells up from place to place and becomes degenerated. The colloidal detritus of these degenerated parenchyma cells becomes more and more resorbed and new connective tissue replaces the crypts, increasing the stroma. In a later state this connective tissue retracts. The tumor does not spread further over the boundary line after the selenium treatment. The tumor becomes, therefore, more and more of the demarginated character of fibroma. But the tumor does not disappear under selenium compound treatment. There are certain practical aspects of the selenium compound treatment in cancer cases. If a radical operation is possible, this should be done. But the success of the operation should be improved by subsequent selenium compound treatment, because this treatment prevents relapses and metastases. In other cases it is possible for a partial operation to be performed, and the residue of the operated tumor can be treated internally and locally with selenium compound. In non-operable cases the selenium treatment is necessary. If the condition of this patient and of the tumor are improved, an operation can be done later on. An operation is not indicated in the state of colloidal degeneration of the parenchyma and soft swelling of the tumor. But it seems that in the state of fibroid retraction of the tumor an operation is very often necessary.

1. **Sterility in Women.**—E. Reynolds says that about ten years ago he reached the theoretical conclusion that in most cases female sterility was produced by abnormal genital secretions destructive to the spermatozoon. While the vaginal secretions are normally acid and destructive to the pathogenic organisms as well as to the spermatozoon, their effect on the latter is normally neutralized in coitus by the alkaline cervical secretions. Any excessive acidity, however, is not neutralized, hence the death of the spermatozoon and sterility. When the cervical secretions themselves are deficient or abnormal, though those of the vagina may not be, sterility may also be a result. It is also probable that the cervical overflow due to congested conditions is in itself a cause of sterility as well as the scantiness and the thickening. Another occasional cause of sterility are abnormalities in the ovaries or tubes, even when slight, but these cases form a more difficult subject for the consideration of the obstetrician. A gross salpingitis is not essential, but sterility may occur even when only one tube is affected from the alterations in the uterine conditions and secretions from the infected tube. The ovary is always affected to some extent, and Reynolds' observations lead him to suspect that even moderate enlargements of these ovaries, with their many persistent fol-

licles, are in a perverted physiological condition. As to the prognosis of sterility two forms of the condition are hopeless or nearly so, viz.: that due to infantile or approximately infantile uterus cannot be treated successfully, and sterility occurring after operations for the removal of tube or portions of ovary is, accordingly, not very hopeful. All other forms of sterility are usually remediable. Sterility due to other causes than infantile uterus can be treated with a satisfactory degree of success. As regards surgical treatment the operative alterations of the cervix in shape and condition which insure perfect drainage, together with dilatation and curettage of the uterine cavity, the correction of displacements or other abnormalities which tend to congestion, the reduction of the ovaries to the normal by a conservative operation, and the elevation of the ovaries and tubes to a position in the pelvis which insures a free venous return from these organs, have been followed by a degree of success not before attained in the treatment of this most difficult class of sterilities.

2. **Intestinal Intoxication and Polyneuritis.**—C. von Noorden describes a special form of intestinal intoxication studied by him, in which there is a certain degree of constipation and retention of fecal contents in the sigmoid flexure; there develops a feeling of fulness after eating, which the patients usually refer to the stomach which empties itself slowly and develops a high degree of acidity. Examination of the abdomen reveals over the sigmoid a certain point sensitive to pressure, which corresponds to McBurney's point in appendicitis, and which is called the S point. Diarrhea may occur instead of constipation, from the irritation of the fecal masses which are retained by spasm of the intestinal wall. In many cases the symptoms are restricted to those mentioned, but in others a peculiar clinical picture appears, wandering pains all over the body from the trigeminal area to the sciatic. The joints may also be affected, and there is a mild polyneuritis with circulatory phenomena indicating irritation in the vagus area, such as slow pulse, extrasystoles, dermography, etc. In the majority of cases an unusual excretion of indican is found. H. Eppinger has been able to extract from the feces of some of these patients a poisonous substance which has a marked effect on the vagus and reproduces the symptoms described in animal experiments. He thinks they have succeeded in isolating a bacterium of the paratyphus group but differing from the known forms. The production of poisons is different in different culture media, but the experiments are not yet sufficient for exact details. Another symptom accompanying the picture is a slight subfebrile temperature variation, which may give rise to suspicion of latent tuberculosis but which disappears when the intestinal function is regulated. The treatment has varied with the varying diagnoses. Usually the first diagnosis is simple neurasthenia or rheumatic trouble; frequently the condition has been confused with myalgia, neuralgia, arthritis, and uric acid troubles, and treatment has varied accordingly, but regulation of the bowels is the necessity. Each case should be studied by itself, and the author prefers dietetic management to the use of laxatives. Usually two or three weeks are sufficient to indicate the line of treatment to be adopted.

9. **Thymus Hyperplasia.**—S. Crotti emphasizes the importance of the use of the *x*-ray in intrathoracic goiter and in thymus hyperplasia. In the last three years he has operated on 150 goiters, of which eighteen were partially intrathoracic and six totally such. He made a practice of using the *x*-ray to corroborate the clinical findings and to detect thymus hyperplasia. From what he found published in regard to the thymus he supposed this complication of goiter was rare, but recent experience has led him to think otherwise. He reports five cases observed lately, three controlled by autopsy and one by operation, and his conclusions are given as follows: Röntgen-ray examination must become part of the routine in goiter work. It is of the utmost necessity in intrathoracic goiter. As a thymus hyperplasia is liable to be found as a complication in any kind of goiter, especially in hyperthyroidism, and as this complication may prove fatal to the patient, the Roentgen-ray examination should be applied in every goiter case. The diagnosis of a thymus hyperplasia is possible in the great majority of cases. Röntgen-ray and clinical examinations must be combined to enable one to reach the correct diagnosis. When the diagnosis of thymus hyperplasia complicating a goiterous condition is made the operation should be postponed and the Röntgen-ray treatment should be applied until a marked diminution of the size of the gland is reached. The thymus gland is very sensitive to the Röntgen rays, especially in children.

13. **Othygroma Nephriticum.**—O. Glogau reports a case of elongation of the lobule of the ear following edema from acute nephritis, a hitherto undescribed disfigurement, for which he proposes the name "othygroma nephriticum." He believes there is some analogy between this condition and othematoma, but as the patient would not permit any operation or the removal of a piece of tissue for examination the pathological conditions cannot be stated.

1. **Insect Porters of Bacterial Infection.**—C. J. Martin notes that the fly carries infection to a greater extent by regurgitating the contents of its crop and by defecation than by carrying bacteria upon its exterior. In studying the relation of flies to typhoid fever, the observation has been frequently made that there is a seasonal correspondence between the maximal prevalence of typhoid fever and that of flies. The same parallelism has been noted in the case of infantile diarrhea. The author concludes from the analysis of many available sources of evidence that the fly-carrier hypothesis is the only one which offers a satisfactory interpretation of the extraordinary dependence of diarrheal epidemics upon the accumulated effect of temperature; that it offers a ready explanation of the spread of infection to neighboring children who have no direct personal contact with the patient, and that the peculiarities of the relation in time between fly prevalence and the epidemic in different localities are not inconsistent with the view that fly carriage is essential to epidemicity.

2. **Recovery in a Case of Acute Streptococcal Endocarditis.**—H. Hemsted reports the case of a married woman aged 21 who had a congenital lesion of the endocardium and became infected from a tooth abscess. Ulceration of the mural endocardium resulted in innumerable infarcts in the lungs and a few in other tissues. Streptococci were isolated on several occasions from the blood-stream, and the patient, after being ill for nearly a year, has completely recovered in spite of many adventures. She was treated with autogenous vaccines and autogenous serum. In the early stages scattered pulmonary infarcts produced a picture closely simulating acute tuberculous pleurisy. The author believes that this

is the first case of this kind in which recovery has been reported. The grafting of streptococcal infection on top of a congenital or other lesion of the endocardium has been recently insisted on by Horder and others, and this case seems to emphasise the danger of allowing microorganisms a chance to invade the blood-streams in cases in which endocarditis exists in a latent form or in which there are congenital malformations. In this case the heart valves were unaffected, and the ulcerated patch of endothelium was situated in the right ventricle around an ostium guarding an extra or infundibular ventricle leading to the pulmonary artery. This condition would have accounted for the great predominance of infarcts in the lungs; the invariable presence of streptococci in the expectorated blood; and the difficulty in cultivating cocci from the systemic veins in the first four months of the disease. It is inferred that there was no leak in the ventricular septum in this case, by reason of the relative paucity of signs in the systemic circulation. The fact of the valves remaining healthy facilitated complete recovery.

4. **Glycosuria in Tuberculous Meningitis.**—R. S. Frew and A. E. Garrod find that glycosuria is by no means an uncommon symptom in tuberculous meningitis, for it occurs in more than one-third of all cases of that disease; that sugar is most apt to appear in the urine during the last days of the patient's life; and that this variety of glycosuria probably has its origin in the cerebral lesion and belongs to the nervous group, but to what special lesion or other factor its occurrence is due the authors have not been able to determine.

6. **Tuberculin Treatment of Tuberculosis.**—N. D. Bardswell states that the dosage of tuberculin given to the patients in King Edward VII Sanatorium in 1907 was never outside the limits of 1/1000 to 1/600 milligram, T.R. being the preparation used in every instance. Thirty cases in all were treated, over periods varying from a minimum of six weeks to a maximum of twenty-five weeks. Thirteen of these cases had less than six inoculations. The remaining seventeen cases were patients with well-marked lung disease. Classified according to to Turban-Gerhart method, twelve would be described as Group II and five as Group III cases. No case of early and limited disease (Group I) was included. The cases then were for the most part of an unfavorable type clinically. (1) *Immediate result*—In the case of all the patients thus treated the injection of the small dose of tuberculin nearly invariably resulted in a satisfactory immunizing response, as shown by the rise in the opsonic index. The repeated immunizing responses were not, however, associated with any appreciable alteration in the clinical condition, in respect to such essential factors as reduction of temperature, diminution in the amount of sputum, disappearance of tubercle bacilli, etc. The author was unable to detect any difference whatever in the progress of the tuberculin-treated patients as compared with the progress of similar types of patients who, living under precisely similar conditions, were not having tuberculin. In no case did the weekly repetition of the small doses of tuberculin give rise to any hypersensitiveness. (2) *Ultimate results.*—Considering only the seventeen cases whose treatment extended over periods ranging from a minimum of seven weeks to a maximum of twenty-five weeks, the results are as follows: Of twelve cases of moderately advanced disease (Group II), after a period of five years since discharge from the sanatorium, four, or 33 per cent., are well, and the remainder are dead. Of those who have died, two lived for over four years, three lived for over three years, two lived for over one year, and one lived three months only after discharge. Two of the four patients who are well lost their bacilli before they left the sanatorium. The five cases of very advanced disease all died within twelve months of their discharge. These results compare somewhat unfavorably with the ultimate results of comparable cases treated in the sanatorium during the same period without tuberculin. The numbers treated with tuberculin, however, are small, so no great importance can be attached to such a statistical comparison. The conclusion that the author seems justified in arriving at is that the tuberculin from a clinical point of view, was a negligible factor, and in no wise influenced either the immediate or the ultimate prospects of the patients to whom it was given.

10. **The Emotional Grimaces of Infancy.**—W. A. Hollis notes that emotional expression is probably reduced to its simplest terms in the newborn—that is, to a pitiful indication of bodily discomfort. In the face a puckered bulge of integument over the forehead at the root of the nose is probably the first intimation an outsider obtains of the child's feelings. Meanwhile, the surrounding features are, as it were, dragged towards this center of motor activity. The nose-tip is tilted upwards and the upper lip tightened. The inner canthi of the closed eyes are drawn together, the eyebrows converge, and the swollen mid-frontal region is depressed. Even the mouth at first is tightly shut, the lips squeezed together, and the chin forced upwards. Soon, however, the jaw drops, respiration becomes spasmodic, and cries are uttered. In seeking to explain the significance of an infant's grimace the author states that a large number of mammals, perhaps a majority, enter life sightless. The human fetus, on the other hand, unlike a kitten or a puppy, is not born with its eyelids sealed for nine days. Yet these screens are seldom raised during that period. The glamour of daylight is doubtless prejudicial to the development of the infant's eyes. For some weeks after birth the quantity and quality of the admitted light is automatically regulated by prolonged closure of the eyelids. Under these conditions the brightest rays of sunshine are so sifted and modified that only waves at the red end of the spectrum—that is, the blood-tinted light which penetrates the translucent lids of the closed eyes—can, as a rule, stimulate the immature retinæ of the child.

1. **Insect Porters of Bacterial Infection.**—By C. J. Martin. (See page 171.)

2. **Gallstones.**—Sir Berkeley Moynihan finds that a very large number of patients—probably, indeed, a large majority—who have suffered for years from "gastric" disorders have no organic disease in the organ impugned, but have a real structural disease in other parts, notably the gall bladder or the appendix. The "inaugural symptoms" of gallstones are briefly recapitulated as follows: The patient complains of a fullness, weight, and distention, or oppression in the epigastrium coming on soon after meals, within half or three-quarters of an hour, relieved by belching, and dismissed almost on the instant by vomiting, elicited with remarkable constancy by certain articles of diet, especially those of a "greasy" nature, and dependent rather upon the quality than upon the quantity of the food. There is a sensation of great tightness, which if unrelieved may become acute pain, from which the patient obtains ease by bending the body forwards, by flexing the right thigh on the abdomen, or by loosening all garments which fit tightly to the waist. There is frequently great complaint of "acidity" or heartburn, and in

the act of belching there may be sour or acid regurgitation. While the discomfort lasts the patient may notice a "catch" in his breath, and he finds, perhaps, that it is impossible to breathe deeply without feeling an acute stabbing pain at the right costal margin. There may be a feeling of faintness and nausea, and, rarely, vomiting may occur spontaneously. After a more than usually severe attack of "indigestion" the body and side may feel stiff for several days. A frequent and a very characteristic early symptom of cholelithiasis is the occurrence during an attack of indigestion of a slight sensation of chilliness, especially in the evenings after a meal. The patient may shiver for several minutes, and may hasten from the table to huddle over a fire. The sensation of "goose flesh" is often experienced, and several medical men upon whom the author has operated have said that in the severer phase it was not unlike a very slight rigor, the chilly stage being quickly followed by one in which the body feels hot and the skin begins to act queerly. The author believes that when once a diagnosis of gallstones has been made, operation is always indicated unless there are grave reasons forbidding resort to surgery.

**3. Problems of Tuberculosis.**—S. Delépine notes that an attempt which has been made of late years to apply very accurate mathematical methods to the interpretation of data of doubtful value has disturbed scientific opinion to such an extent that facts capable of clear experimental proof are now doubted. Heredity, which had ceased to be considered as having more than a secondary share in the spread of tuberculosis, is once more brought forward as a factor of first importance. The very wide distribution of the *Bacillus tuberculosis*, and the fact that the great majority of people have at one time or another been harboring the tubercle bacillus and yet have recovered, as well as the analysis of returns of very unequal values, have led some statisticians, Karl Pearson, for instance, to doubt whether tuberculosis should be considered as an infectious disease in the ordinary sense. Such views, if correct, would strike at the root of all modern methods of prevention of tuberculosis. The importance of predisposing factors is often so great that not a few clinicians and administrators have given but scant attention to the essential cause. It must be acknowledged that in many cases it is possible to obtain excellent results by dealing thoroughly with predisposing causes, and often there is no other course open. It is, however, never safe to disregard, even temporarily or partially, the *causa causans*, because it is liable to variations and may, under the influence of circumstances, acquire infective powers exceeding the average. Neither is it safe to trust entirely to the action of natural or artificial curative agencies. Recoveries from infectious diseases may be apparent or real, and do not invariably result in so great a reduction in the number of infective centers as might be expected. Recoveries brought about by natural processes introduce an additional element of complexity in one's estimates of the incidence of various infectious diseases. In studying the conditions which influence the prevalence of any infectious disease one must, therefore, take account of the possible action of a great number of factors, which may roughly be grouped into the following categories: (1) distribution and habits of the infecting parasite; (2) conditions influencing the quantity of the parasite; (3) conditions influencing the virulence of the parasite; (4) opportunities and channels of infection; (5) conditions influencing the resistance of the possible host; and (6) proportion and completeness of recoveries.

## Berliner klinische Wochenschrift.

*December 30, 1912.*

**Gallstone Ileus.**—Tietze has done 100 operations for ileus in general during the past seven years. Naturally, the great quest at the present time is to diagnosticate the cause and seat of the obstruction and the various types of ileus. Wahl, a recent writer, distinguishes sharply between obturation and strangulation ileus, and there are many points of difference between strangulation and paralytic ileus, although diagnosis is not always easy. It is also necessary to exclude peritonitis in these cases. The author now takes up gallstone ileus. An elderly woman had been vomiting bile and complained of colicky pains. Soon the vomitus took on fecal characters. At the same time other evidences of a stoppage were apparent. There was no history pointing to similar antecedent troubles. Abdominal palpation showed the presence of peristalsis. The vomiting showed a cyclical character. This was sufficient for a diagnosis of obturation ileus in the small intestine. There were two minor points in the history regarded as significant, to wit, intolerance of the stomach to cold drinks and a vague history of gastric disturbances (the patient had denied positively both biliary colic and gastralgia). There was some biliary matter in the urine. The diagnosis was then made of gallstone ileus, so that the resulting laparotomy was not exploratory in intent. A large stone was at once located and removed. Others were sought for in vain. The patient continued to vomit and thirty-six hours later the gall-bladder was exposed and found adherent to the stomach and duodenum as a large, firm conglomerate. The patient succumbed after the second operation, and autopsy showed that the stone had ulcerated into the duodenum.

**Experimental Chemotherapy of Bacterial Infections.**—Levy reports some work with the promising parasitotropic substance ethylhydrocuprein. He had already shown that the latter could antagonize successfully the experimental pneumococcus septicemia of mice. It therefore became desirable to test it in other like forms of disease due to other bacteria. It was soon learned that the drug was inert against the *Streptococcus longus*. The coincidence was remarked that the pneumococcus unlike its own congeners behaved in some ways like the protozoa which are also known to be reached by parasitotropic remedies. Thus pneumococci dissolve readily in bile and solutions of biliary acids. Using this as a standard the author tested the behavior of other bacteria toward bile, and soon learned that the *Streptococcus mucosus* also dissolved in bile acids. Mice were then inoculated with cultures of the same and experiments showed fully that even in the full bloom of a mucosus infection the latter could be controlled by ethylhydrocuprein. The untreated control animals succumbed promptly.

**Diffuse Purulent Peritonitis from Diverticulitis.**—Pollnow reports a case in which a subject with a Meckel's diverticulum developed a violent abdominal crisis. During a previous attack of appendicitis the appendix was removed, and the presence of the diverticle was noted. However no resection was performed. The woman was now three months pregnant. Diagnosis was made of adhesion ileus probably combined with peritonitis. The surgeon who had operated before was called in and performed laparotomy, and found fecal matter in the peritoneal cavity. The perforation was found to have occurred in the now gangrenous Meckel's diverticulum. The precise evolution of the condition was as follows: 1. Chronic diverticulitis. 2. Adhesion ileus secondary to same. 3. Incarceration and grangrene of inflamed diverticle. 4. Perforation of same and general peritonitis. The treatment consisted in extirpating the gangrenous diverticle, replacing the twisted loop of intestine, irrigation of peritoneal cavity, and infusing 50 c.cm. of 2 per cent. camphor oil. The bowels soon moved. Two days after operation abortion occurred and curettage was done. Fever persisting on sixth day the abdomen was reopened and several abscesses opened and drained.

## Insurance Medicine.

**Conservation of Life as Affecting Life Insurance Companies.**—Dr. P. D. Gold, Jr., of Raleigh, N. C., read a paper entitled "Conservation of Life as Affecting Life Insurance Companies" before the American Association of Medical Examiners, Atlantic City, June 4, 1912. In dealing with this subject the speaker pointed out that we are confronted with difficulties in obtaining sufficient statistics to present a definite or exact amount of the benefit that is received. No life insurance company has conducted a campaign of life conservation long enough to produce data that are of value. Attention was drawn to the fact that the average life is not the same the world over. Life insurance statistics are based on the death rate of the insurable class and general vital statistics include both the insurable and the non-insurable class. Therefore, analyzing the application of conservation of life to these figures, we realize we are attempting to apply an uncertain quantity to a business based on mathematical averages. Dr. Gold entered into a consideration of figures and details bearing on the matter which we have not the space to discuss here. He concludes that every assistance, every encouragement that can be given to efforts for human welfare and life prolongation should receive the hearty support of life insurance organizations. Individual companies should not be expected to bear the burden alone, for the varied interests are so interwoven that all would receive the benefits from the efforts of the few. United action alone can ensure a full realization of our ideals.—*Lancet-Clinic,* November 23, 1912.

**Life Insurance and Carious Teeth in Septic Mouths.**—The series of articles on the above subject, contributed by authorities, which have been running in *Oral Hygiene,* closed in the issue of that journal for September, 1912. In conclusion it is stated that one purpose of the series of articles has been to focus attention on the contributions that diseased, decayed, deformed and deficient teeth, and their faulty artificial substitutes, make to the sum of the etiological factors involved in the excitation and continuation of diseases and disorders considered. The purpose of medical examination for life insurance is to protect the companies from accepting undesirable risks. The study of many deadly diseases convinced one that deformed, decayed and diseased dental organs are a direct or indirect, indisputable contributor to the cause. This being true, and the function of the insurance medical examiner being to eliminate undesirable risks, and to detect any present or potential danger of disease, very logically the mouth should receive the same careful examination as other vulnerable organs. 2. It will increase the companies' business in another way, namely, by a medical or dental examiner suggesting to an applicant that if certain correctible conditions are remedied, the application will be successful. This will have a psychological effect. The minute you say to a man or woman "You cannot have such a thing until certain things are remedied," that minute the desire for the thing is increased, the conditions will be corrected and the business of the company will be further augmented. 3. The mere fact of an insurance company requiring and instituting this dental examination will be a further advertisement of the care with which it selects its policyholders, and will attract new business for this reason. 4. It will decrease the losses of the company. If this be all true, what good will it do the policyholders, present and prospective? 1. Whatever benefits the company benefits the policyholders in some way. 2. The policyholder, after a dental examination, will have at least the assurance that if the hygiene of the mouth is maintained and his dental organs, natural or artificial, are in a sound condition, he must expect to live longer, have less liability to disease, and will not have to die to collect his endowment policy. 3. It will supply him with the most powerful incentive to get and maintain his teeth in a proper condition, for has he not had it brought home to him that the greatest business in the world says, "Sound teeth are necessary to prolong life and guard against disease"? And has he not just had them repaired at some expense to himseld? 4. If diseased teeth are a menace to the health of the individual, very certainly they are a menace to the health of those with whom he comes in contact. 5. If proper dental attention is a guard against disease, it must very certainly be no passive promoter of good health, good looks, good morals, and good thoughts.

**A Proposed Reform.**—Flesch refers to the efforts of insurance companies to suppress, as far as possible, all avoidable mortality of the insured. Medical selection, however strict, is not enough in itself. Shortening the term of insurance is a factor of no little importance but this lowers the total value of the insurance to the public and is also difficult to carry out. Mortality is due to two groups of factors, endogenous and exogenous. The former include heredity, and the status up to the time of selection. Careful medical examination will weed out much of the bad possibilities of endogenous factors. Exogenous causes come under four heads, viz.: bacterial infection, traumatism, intoxications and neoplasms. This responsibility here may, to a large extent, be put up to the insured himself, who should be informed accordingly. Example—a risk develops a severe facial neuralgia, and, not finding relief, commits suicide. This risk may have no means of knowing that deep alcohol injections and gasserectomy can give him permanent relief or at least a prolonged respite. Again, a risks suffers from chronic otitis media, which is unrelieved by conservative management. He ought to be told that his life is seriously menaced, and that a radical operation, with practically no peril to himself will rid him from this menace. The author expresses his belief that a course of tuberculin injections can so retard the development of dementia paralytica that the risk may outlive his insurance period.—*Zeitschrift für Versicherungsmedizin,* 1912, V, Heft 10.

**Medical Section of the American Life Convention.**—The third mid-year meeting of this Society will be held at Hot Springs, Arkansas, on February 26, 27 and 28, under the presidency of Dr. H. A. Baker. Papers will be read by Mr. Isaac Miller Hamilton, President of the Federal Life; Mr. Virgil M. Kime, Associate Actuary of the American Central Life; Dr. J. T. L. Battle, of the Southern Life and Trust; Dr. W. S. Kendrick, of the Southern States Life: Dr. James H. Wroth, of the Occidental Life; Dr. C. R. Dudley, of the Missouri State Life; Dr. H. B. Miller, of the Security Mutual Life; Dr. M. D. Silver, of the Michigan State Life, and Dr. George W. Combs, of the Reliable Life Insurance Company.

Blumenfeld, Spezialarzt für Nasen-, Hals-, und Limgenkrankheiten in Wiesbaden. I Bd., 2. Hälfte, Lieferung 6; price 4.50 marks. II. Band, Lieferung 1, price 6.50 marks. III Band, Lieferung ¾, price 14 marks. IV. Band, Lieferung 3, 4, price 8.50 marks. Würzburg: Curt Kabitzsch (A. Stuber's Verlag,) 1912.

The wide scope and superb execution of this work have already been referred to in these columns in the reviews of the earlier parts that have been issued. The sixth installment of the second half of the first volume begins with an article by Edmund Meyer on the phlegmonous inflammations of the upper air passages. This is followed by an article on the septic diseases by Kissling, of Hamburg. The first installment of the second volume contains a full and admirably illustrated article on the injuries and surgical diseases of the external ear by O. Voss of Frankfort a. M. The third and fourth installments of the third volume contain the conclusion of the article on the operations of the accessory sinuses of the nose by Boeuninghaus, and the remaining 200 pages are devoted to a most extensive and complete exposition of the subject of intranasal surgery by L. Katz, one of the editors of the entire work. The full page plates, mostly colored, as well as the other illustrations, are particularly numerous, and like all those that appear in the other sections of this monumental work represent the finest examples of the artistic illustration of medical books. The third and fourth installments of the fourth volume contain the concluding pages of the article on the surgery of the thyroid by Gluck and Soerensen, an article (really a monograph) of 114 pages on the subject of laryngofissure by Hansberg of Dortmund, and the beginning of an article on endolaryngeal operations by F. Blumenfeld of Wiesbaden.

Pathology and Treatment of Diseases of Women. Fourth edition. Rewritten by A. Martin, Professor and Direktor, and Ph. Jung, Professor and Oberarzt der Universitäts-Frauenklinik in Greifswald. Only authorized English translation, written and edited by Henry Schmitz, M.D., Professor of Gynecology, Chicago College of Medicine and Surgery, Medical Department, Valparaiso University; Attending Surgeon, St. Mary's of Nazareth Hospital; Attending Gynecologist, Frances E. Willard National Temperance Hospital, Chicago. With 187 illustrations, 25 of which are in colors. Price $5.00 net. New York: Rebman Company, 1912.

This is a handsome volume of 475 pages and represents the first English version of the fourth edition of the well-known work of Martin and Jung. The chief virtues of this book are its conciseness, the admirable classification of the various gynecological ailments, and the exceptionally complete presentation of the subject of treatment. The needs of the general practitioner are amply supplied in the full discussion of the office and now surgical treatment of diseases of women, while the demands of the surgeon are met in the detailed description of the various operations. The illustrations, which are numerous and of artistic merit, are particularly helpful. The book is well adapted for didactic purposes by virtue of the systematic arrangement of its subject-matter and the black-face side-headings and important words in the text. Non-essential, doubtful, and controverted points are excluded, and only facts, most of which have been verified by the authors' own experience, are given a place. The translator has rigidly adhered to the German text, which probably accounts for the rather cumbrous and complicated style, which makes the reading somewhat difficult. The book may be recommended to the practitioner and gynecologist as one representing modern gynecology from the German standpoint.

Diagnose der Simulation nervöser Symptome. Ein Lehrbuch für den Praktiker. Von Priv.-Doz. Dr. Siegmund Erben, Wien. Mit 24 Textabbildungen und 3 Tafeln. Price 8.50 marks ($2.15). Berlin und Wien: Urban & Schwarzenberg; New York: Rebman Company, 1912.

A most interesting domain of medicine is explored in this textbook, which deals with the important subject of recognizing the various manifestations that simulate nervous symptoms. This subject is one that appeals to the general practitioner and to the neurologist, but more particularly to the medical examiner of accident insurance companies and to medicolegal experts. The author covers the ground with the thoroughness characteristic of the German investigator. The text is subdivided under the following headings: Nervousness, nuerasthenia, and the traumatic neuroses; anesthesia, hyperesthesia, and paresthesia; pain and hyperesthesia; motor symptoms; vertigo; malaise; attacks of fainting, epilepsy, and hysteria; coma; and idiocy.

The Blood: A Guide to its Examination and to the Diagnosis and Treatment of its Diseases. By G. Lovell Gulland, M.A., B.Sc., M.D., F.R.C.P.E.; Physician to the Royal Infirmary and to the Royal Victoria Hospital for Consumption, Honorary Physician to Chalmers Hospital, Lecturer on Medicine at Surgeon Hall, Edinburgh; and Alexander Goodall, M.D., F.R.C.P.E.; Lecturer on Physiology and on Practical Medicine at Surgeons' Hall, and on Diseases of the Blood in the Edinburgh Postgraduate Courses in Medicine; Examiner in Physiology to the Royal College of Physicians, Edinburgh. With 16 Text illustrations and 16 colored Plates. Price $5.00. New York: E. B. Treat & Company, 1912.

The subject of the blood and of its diseases comprises a distinct branch of clinical medicine, the mastery of which requires practically a lifetime of special study. For this reason it would seem as if the expert hematologist alone is competent to pass upon the diagnosis and treatment of such conditions as pernicious anemia, the various leucemias, etc. Medicine has not as yet reached this stage of specialism. The general practitioner must undertake the management of these cases, but in doing so he must rely upon the findings and advice of the clinical pathologist in making his diagnosis and in checking up his therapeutic results. The present volume is a most valuable contribution to the literature of hematology, for it combines in the rather unique manual the qualities of a guide-book both to the clinical pathologist and to the internist. It discusses the histology and physiology of the blood; the technical steps and methods employed in the examination of the blood; the changes in the blood occurring in various diseases; the clinical picture of the various diseases characterized chiefly by the accompanying changes in the blood; and the methods of treating these diseases. The latest advances in the subject of hematology are fully presented in this work. The chapters on the tropical blood diseases are particularly valuable in view of the recent impetus given by the study of tropical diseases. The work bears the imprint of ripe scholarship, and is exceptionally well written. The illustrations and particularly the colored plates are of a high order of artistic merit. The volume may be recommended without hesitation as one of the best treatises on the subject that has appeared within recent years. The consummate art of the publisher is seen in the unusual excellence of the paper, type, and binding.

Cerebellar Functions. By Dr. André-Thomas, Ancien Interne des Hôpitaux de Paris. Translated by W. Conyers Herring, M.D., of New York. With 80 Figures in the Text. Nervous and Mental Disease Monograph Series No. 12. Price $3.00. New York: The Journal of Nervous and Mental Disease Publishing Company, 1912.

The subjects of the physiology, the pathology, and the nerological significance of the cerebellum have undergone considerable development within the past few years. A complete exposition of the current knowledge of these subjects is presented in this excellent monograph by André-Thomas. Part first sets forth the facts under the headings of anatomy of the cerebellum, experimentation and destruction of the cerebellum, and symptomatology of the affections of the cerebellum. Part second presents an interpretation of these facts. It discusses the cerebellum, and the organic functions, the cerebellum and sensibility, the cerebellum and intelligence, and the cerebellum and motility. An extensive bibliography concludes the volume.

The Blood of the Fathers. A Play in Four Acts. By G. Frank Lydston, Chicago: The Riverton Press, 1912.

This work by Dr. Frank Lydston is somewhat of a problem play, a study in heredity and environment. It is a play with a purpose, a plea for the betterment of the race mentally and physically by social and scientific means. The plot is ingenious and the play is written with a considerable amount of power.

## SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

*Twenty-fifth Annual Meeting, Held at Old Point Comfort, Virginia, December 17, 18 and 19, 1912.*

The President, Dr. J. M. T. Finney, of Baltimore, in the Chair.

**Intestinal Obstruction, with a Clinical Study of One Hundred and Eighty-One Cases.**—Dr. Alexius McClannan, Baltimore, stated that the form of operation required in any given case must depend on the nature of the obstruction and on the presence or absence of complications. Thus we grouped the operations performed into three classes, namely, relief of the obstruction, excision of intestine, and enterostomy. In order to judge the efficiency of any of these operations it was necessary that the procedures be compared with regard to the stage of the disease at which the operation was performed. This was the only logical basis for study of the treatment of obstruction and avoided the confusion of many classes as to causation, differences in position of the obstruction, and variations in the completeness of the occlusion. Each of these factors altered the rapidity of development and the duration of the three stages of the disease, consequently a study of intestinal obstruction from the point of view of the symptomatology and treatment of these stages balanced the relation of the various factors and made the comparison of operative statistics possible. Of thirty-four patients treated in the first stage, all recovered. Of these twelve were relieved of their symptoms by enemas and purgatives. The other twenty-two were operated upon; in fifteen the obstruction was relieved; resection was performed in three cases; enterostomy with short circuiting and enterostomy with relief of obstruction once each. Simple enterostomy was done twice. Relief of the obstruction, therefore, was the best operative procedure in cases treated during the first stage. When provision had been made for a delayed enterostomy, this was the best procedure in post-operative obstruction, probably because opening the previously brought up loop gave no operative shock. Sixty-five patients were operated upon in the second stage, fifty-five recovered, eleven of these died as a result of a second operation or some complication developing later than one week after the original operation. The operations performed were as follows: Relief of obstruction, forty-four, six fatal; short circuiting, two; excision, fourteen; enterostomy, four; enterostomy, with other operations, fifteen. One patient was relieved by an enema. Gangrene was present in ten cases; two were treated by anastomosis and excision; eight patients recovered; six were resected. Relief of the obstruction seemed the best operation in the second stage, provided gangrene had not developed. In the presence of gangrene resection was the best operation, provided the constitutional symptoms were not pronounced. In the latter event, enterostomy should be added to the resection, or if the condition of the patient was grave the loops might be brought out of the abdomen packed off with gauze, with an enterostomy above the obstruction. Eighty-two patients were operated on in the third stage; fifty-two died. Relief of the obstruction was done in 22 per cent. of the cured, 34 per cent. of the fatal cases. Enterostomy and relief in 22 per cent. of the cured, 8½ per cent. of the fatal. Simple enterostomy in 45 per cent. of the cured, 32 per cent. of the fatal cases. Enterostomy with other operations in the remaining cases, three cured, and nine fatal. Resection was done in one fatal case, and extrusion in two others. One patient was relieved by an enema and five died without operation. Gangrene was present in fifteen cases, two cured and thirteen fatal. In both the cured cases enterostomy and excision were done. In the third stage enterostomy should be done, either alone or in connection with the other procedures. In the non-gangrenous cases enterostomy was done in 77 per cent. of the cured and in but 41 per cent. of the fatal cases.

Dr. Joseph C. Bloodgood of Baltimore said that Dr. McClannan was the first to publish a large number of cases showing the importance of the effect of washing out the stomach and of giving enemas to aid in the early diagnosis of intestinal obstruction, a thing always neglected outside of the hospital, and often neglected in the hospital, namely, the importance of the stomach tube and enema in the differential diagnosis. In going over his cases years ago he was surprised at the difference between the mortality of cases of intestinal obstruction taking place in the hospital and those outside of the hospital. Those in the hospital had just been subjected to operation, and, therefore, were not considered good operative risks, yet the mortality from post-operative obstruction was much less than it was outside, due to the early recognition of the obstruction, and in the majority of cases early diagnosis had been made by the use of the stomach tube and enema.

Dr. Henry T. Byford of Chicago stated that one point in the treatment which it was necessary to consider, and one which involved the early diagnosis, was whether the obstructed gut was going to result in gangrene or some permanent injury, or whether the patient could be carried along for awhile without any resulting injury. In post-operative cases, in which there was a kink in the intestine or adhesions sufficient to cause paralysis, if we were in doubt as to whether there was really an obstruction or adhesions sufficient to cause paralysis, if we could introduce two or three quarts of fluid into the system we might be able to carry the patient over a week or more, so that there would not be any gangrene, as in a case of volvulus, intussusception, or hernia, and this explained why cases got along better in a hospital than those outside of such an institution.

Dr. John Young Brown of St. Louis said the importance of draining the distended loop of bowel above the obstruction could not be too strongly accentuated. A number of years ago, in a paper he read before the Mississippi Valley Medical Association, he reported a series of cases in which he resected the gangrenous gut and described a method of draining the loop of intestine above the obstruction, namely, to cut across the bowel, introduce a tube into the bowel, and while an assistant was handling the bowel above, the resection was made without losing any time. The use of the stomach tube and rectal tube, both before and after operation was of exceeding importance.

Dr. Ernst Jonas of St. Louis said that early operation in cases of intestinal obstruction by a poor operator was preferable to a late operation by the most experienced surgeon. The doctor should be warned about giving cathartics by mouth if there was any doubt as to intestinal obstruction. Cathartics in these cases aggravated the condition. If enema and lavage did not relieve the patient, preparations for operation should be made.

Dr. I. S. Stone of Washington, D. C., said that purgatives not only did harm, but they were rarely indicated. With the use of eserin and enemas, properly given, he had never seen a purgative necessary. Since he had been using that combination he had never found a secondary operation necessary where the conditions were not most formidable where that simple method of treatment was properly tried.

Dr. James E. Moore of Minneapolis wished to emphasize the axiom laid down long ago by Craig Smith, that the distended bowel should be relieved by making an opening into it.

Dr. Samuel J. Mixter of Boston, Mass., said in looking back on the fatal cases of intestinal obstruction it would be found death occurred in those cases where the intestine had not been emptied, or where an anastomosis had been done immediately and the septic contents of the occluded intestine had been poured into the lower intestine. Abbé pointed out that the intestine below was starved and ready to take up the material poured down from above, and in that way a rapid and fatal sepsis ensued.

Dr. Charles H. Mayo of Rochester, Minn., said in the last year, in cases of intestinal obstruction, they had in four cases through the appendicostomy incision been able by drainage to overcome the immediate obstruction.

Dr. Joseph Ransohoff of Cincinnati, Ohio, called attention to the use of the *x*-ray in locating the obstruction in acute cases. Outside of hospitals, this was out of the question, but when a patient was brought into the hospital it took but a short time to get an *x*-ray picture, and in three recent cases the obstruction was located by this means.

Dr. Robert T. Morris of New York City stated that for a year or more he had been using injections by rectum of bismuth solution, also using it by the stomach as far as possible, and then employing the fluoroscope, and in this way determining definitely the seat of the obstruction.

Dr. William D. Haggard of Nashville called attention to enterostomy as a temporary measure in saving the patient's life. He did four enterostomies last year, in three of which the patients required no secondary operation. They were all saved.

Dr. H. A. Royster of Raleigh, N. C., said if there

was retention of scybalous masses and the bowel was gripped on something and could not release itself, if the gut was much distended, and the patient was vomiting, with very little or no pain, we could give a few doses of eserin, say one-fourth of a grain of the salicylate, every two or three hours, until two or three doses were given, to be followed by an alum enema. If the patient was in great pain we could give one-hundredth of a grain of hyoscin, to be followed two hours later by an enema. With this treatment he had found some cases did not need operation at that time, and operation could be safely done later, while other cases did not need operation.

Dr. J. M. T. Finney of Baltimore said he had used the appendix after the method mentioned by Dr. Mayo in eight or ten cases of intestinal obstruction, and in his experience it did all that Dr. Mayo said it did, and it was a very valuable aid in those cases where the obstruction was low down. The indiscriminate use of eserin was followed by disastrous results. His attention had been called to the fact by Dr. Abel of the pharmacological department of the Johns Hopkins Hospital, that eserin under ordinary circumstances had a marked depressing effect. In one case it apparently had a very alarming effect. In one or two others it was followed by marked symptoms of depression, but its withdrawal was followed by decided improvement.

Dr. Rufus B. Hall of Cincinnati emphasized the point made by Dr. Brown in reference to draining the intestine above the seat of obstruction in those cases where it was thought best at the time of the operation to resect the gut. He had used the method advocated by Dr. Brown in a number of cases with satisfactory results. As to the use of eserin, he had seen a number of cases in which there was depression following its administration, and he usually gave it in no larger doses than one-fortieth of a grain.

Dr. Randolph Winslow of Baltimore said that neither eserin nor any other agent was going to relieve a patient when the intestine was mechanically obstructed, and there was nothing to do but to operate. Eserin could only do good in cases in which the bowel was not mechanically obstructed.

Dr. Henry O. Marcy of Boston said the earlier we operated in cases of intestinal obstruction the better. The lives of many patients were lost by delay. When the diagnosis was made it was not only important to determine to operate, but how soon to do so.

Dr. J. Wesley Bovée of Washington, D. C., had been using eserin as a routine in every case after operation ever since Dr. Craig of Boston brought it to the attention of the profession. It never failed to produce a bowel movement in a case in which there was no intestinal obstruction.

Dr. W. W. Crawford of Hattiesburg, Miss., had personal knowledge of a patient who was given one-fiftieth of a grain of eserin by mistake, and who was greatly prostrated by it, so that for two or three hours death seemed imminent. However, the patient did not die. Another patient, a clergyman, to whom he administered one-fortieth of a grain of eserin on the second or third day after the operation, told him he felt as though a stick of dynamite had exploded within him.

Dr. Gordon K. Dickinson of Jersey City said the diagnosis of intestinal obstruction was so uncertain in many instances that to wait until it was made definitely would be to wait until it might be too late to do any good. It was better to go in and tap the gut, and, if necessary, give saline solution subcutaneously, and resort to such other measures as might be demanded.

Dr. Robert Milne of London, England, said it was very fashionable in the London Hospital to give eserin, but it was only the extreme cases of distention that responded to the use of eserin. They did not give more than one-hundredth of a grain at a dose, and they did not give more than three such doses. He could not say that in any of the cases they had noticed any particular collapse from the use of the drug.

Dr. O. H. Elbrecht of St. Louis related some experiments with eserin on normal individuals. He found that small doses had absolutely no effect in many instances, whereas larger doses gave prompt action of the bowels. He found it was usually twenty minutes to half an hour before it acted.

**Pancreatic Cysts.**—Dr. Lomax Gwathmey of Norfolk, Va., reported a case of cyst of the pancreas, and said the fluid content from the large cyst showed considerable detritus, few degenerated epithelial cells and leucocytes, but no cholesterin crystals. The small cyst showed a few degenerated epithelial cells. Attempts to cultivate the organism from the cyst contents were futile. The cyst presented one or two interesting features. The fluid in the large cyst was entirely different from that in the smaller cysts, the difference being due to a hemorrhage or hemorrhages that took place in the large cyst. The smaller cysts were lined by epithelium, while in the large cysts not a vestige of epithelium could be found. The large cyst was evidently lined by epithelium, but this epithelium must have suffered autodigestion. The cyst was at one time uniformly colloid. A hemorrhage or hemorrhages took place in the large cyst, which caused the difference in the cyst contents, and which produced some trauma to the epithelium of the cyst wall, thereby allowing the ferments in the cyst contents to digest the epithelial lining. So lax was the abdominal wall after the removal of the tumor that the appendix was removed without difficulty through the same incision. It contained an extremely large appendolith in the tip and was actively inflamed. Old and fresh adhesions in the pelvis were broken up, adherent coils of small intestine removed from the cul-de-sac, and sigmoid properly placed in the pelvis. The kidneys, liver, gall-bladder and ducts, the pancreatic head, and other abdominal organs were found normal. The wound was closed without drainage. The convalescence was smooth and uneventful, and the patient left the hospital in nineteen days to go to her home in Chicago. A recent letter, six months since her operation, reported her in excellent health, much better than she had ever before experienced.

Dr. Rufus B. Hall of Cincinnati said that several years ago he reported to the association an operation for pancreatic cyst. In that case the cyst evidently arose from trauma. The man was lifting and injured himself. He came to operation five or six months after injury with an enormous tumor in his abdomen, which held more than 2½ gallons of fluid. He simply drained the cyst and stitched it to the abdominal wall. The man died from inanition the seventeenth day after the operation.

Dr. Joseph Ransohoff of Cincinnati reported five cases of pancreatic cyst on which he had operated.

**Increase of Newer Abdominal Surgery Due to Increase in Toxic Disturbances.**—Dr. Robert T. Morris of New York pointed out that cobweb adhesions in the attic of the abdomen belonged to the toxic group of manifestations, and said we were learning a great deal concerning how these toxic impressions lead to the formation of adhesions in cases without an acute inflammatory onset. In some instances bacteria penetrated the wall of the bowel. The endothelium was shed as a result of their presence and the lymph which exuded became disorganized and formed permanent adhesions that were common in the region of the cecum, largely in the region of the sigmoid, and largely in the region of the pylorus and the bile tract. Why were we having more abdominal surgery relating to Lane's kink, to Jackson's membrane, to cobwebs in the attic of the abdomen, than we ever had before? For the answer we should turn to the statistics which were being collected by the Equitable Assurance Association of New York. This company found a rapid increase in insanity and a rapid increase in the number of cases of arteriosclerosis. They found a rapid increase in the number of cases which belonged to the stage of decadence. When there was arrested development as a result of the decadent change that was now taking place in all the civilized nations in our present cultural period, physical defects or stigmata, as classified by psychiatrists, were increasingly in evidence. What were we going to do about it? Surgery had a place in a number of this group of cases and could afford much help, but the other part of the question related to a better development of individuals in the race. It was a question which was not under the control of the surgeon, but belonged to the physiologist and to the eugenist, and surgery, he believed, was very important in that it would require a higher degree of skill on the part of the surgeon decade after decade, and it would require him to be more alert and better able to analyze cases than he had been able to do before. There would be more Jackson membranes, more Lane's kinks, and more adhesions than before, due to the increasing toxic conditions which belonged to the decadent stage of our cultural period.

**Fractures Into and About Joints.**—Dr. Charles E. Caldwell of Cincinnati said the subject of fractures was too perfunctorily taught. A clearer understanding of their nature and complications would bring about better results and obviate many lawsuits. Fractures into and about joints required more discriminating diagnosis and treatment than the average fracture of the shafts of long bones. Crepitus was valuable, and its absence significant. Perfect apposition of fragments was of more conse-

quence in proximity to joints. The author considered fractures about the shoulder, and said that fractures of the anatomical neck were rare. In fracture dislocations, there was necessity for the removal of the head where reduction could not be accomplished. He pointed out the indications for operation, as well as contraindications, in fractures of the surgical neck. He likewise discussed the indications for operations in fractures about the elbow, mentioned the varieties, the diagnosis, and manner of reduction. He also discussed the treatment of fractures at the hip, and about the knee, as well as fractures about the ankle, their varieties and complications.

Dr. Randolph Winslow of Baltimore said he had had a number of cases of fracture of the surgical neck of the humerus, and he had found it impossible in some cases to effect reduction until the arm was drawn into a position of extension and the bones held together by means of screws, and he had had some good results by that method.

Dr. A. A. Law of Minneapolis stated that in the University of Minnesota they had a different procedure from that mentioned, and their results had been different from those related by Dr. Winslow. They resorted to the treatment suggested by Maxwell and Ruth in old people rather than let them be up and about, with the prospect of a deformed joint and a lack of function of the joint. One woman, 87 years of age, and another 92, had functionating joints and union by following the Maxwell-Ruth method. This method in old people was attended with uniformly good results.

Dr. Robert T. Morris of New York said that in cases in which we did not wish to do an open operation we could often, in selected cases, do a simple operation. First, put the limb behind the fluoroscope. Second, run a narrow-bladed knife down near the fracture. Third, put in a cannula. Fourth, run a drill through the cannula, and transfix both fragments. Fifth, run in a silver pin and leave it there, taking everything else out. One could pin a whole lot of fractures behind the fluoroscope with the patients under the influence of cocaine. This method did away with the disadvantage of keeping these patients in bed. In many cases of fractures in joints one could put in a pin and do a simple operation.

**Experimental Anatomical and Physiological Observations Bearing Upon the Total Extirpation of the Colon.**—Dr. August Schachner of Louisville said that when we considered the arrangement by which 20 or more feet of small intestine were being supported through a peritoneal attachment measuring 5 inches, the weakness of the abdominal wall in the inguinal region and the hernias that resulted from the gravitation of abdominal contents against this lowest and weakest point, if we compared the darkened lungs of the human subject with the clean pink lungs of the quadruped living under the same condition as a proof of how unequal the cilias were in their efforts to lift the dirt and bacteria-laden mucus against gravity, and when we watched the pathetic efforts of the tubercular subject to raise against gravity his expectoration, we got the full swing of the disadvantages of the upright position. Mr. Arbuthnot Lane through his work that extended over more than ten years, and especially his recent writings, together with Elias Metchnikoff, deserved the credit for calling the attention of the world to the injurious effects of intestinal stasis. While the end-to-end anastomosis was functionally the most natural, the end to side had the advantage of more security and practically the same advantages that applied to end-to-end. His experimental work justified him in believing that when an ileorectostomy, or ileosigmoidostomy was made by the lateral method, the intestinal contents did not pass through this opening as a rule, but continued the natural course through the colon provided no obstruction existed. In other words, it was a repetition of what occurred in the stomach after gastroenterostomy with a patulous pylorus. The work of Metchnikoff plainly suggested the chemical side of the question, that is, the chemistry of the large intestine when its functions were for any length of time interfered with. The influence of an abnormally movable kidney as a factor in the development of splanchnoptosis, had not received the attention it deserved. Few of us perhaps realized that the retroperitoneal position of the kidney when making excursions, enabled it to dissect loose through attrition the peritoneal attachment that served to anchor the viscera to the vertical column. He wished to emphasize the point that the problem was comprehensive enough to accept all the assistance it could through gymnastics, bandages, regulation of diet and habits, and still furnish an abundant percentage of human wreckage, as Mr. Lane expressed it, for the surgeon to attempt to reclaim.

**The Value of Complete Physiological Rest of the Large Bowel in the Treatment of Certain Ulcerative and Obstructive Lesions of This Organ.**—Dr. John Young Brown of St. Louis, Mo., pointed out the advantages of complete physiological rest of the entire large bowel in the treatment of certain diseases of this organ which had heretofore been treated by some of the surgical methods and described a technic by which this rest could be accomplished, and when its purpose had been fulfilled the bowel could be put back into commission in a manner both safe and satisfactory. Through a right rectus incision sufficiently long for general exploratory purposes, the abdomen was opened. The cecum was at once sought and the large bowel was carefully examined from cecum to sigmoid. All pericolic adhesions were then severed, the appendix removed and the stump buried. The ileum was next severed between two clamps, close to the ileo-cecal valve. The distal ileum was tied off and buried as was the appendix. At a suitable part of the cecum, a purse-string suture of linen was placed and the cecum was next incised. Through this incision, a large rubber catheter was inserted after which the purse-string was tightly tied. A second purse-string of No. 1 chromic catgut was next placed. Under the loops of this purse-string, three long catgut fixation sutures were placed. A stab-wound was next made at McBurney's point through which a forcep was inserted. The catheter and fixation sutures were grasped in the bite of this forceps and pulled through the stab-wound. The peritoneal surfaces of the cecum surrounding the catheter were next scarified and the catheter was pulled through the stab-wound, carrying with it the three fixation sutures. The catheter was now slipped through the button and the fixation sutures were threaded through the eyes in the button and tightly tied, thus closely approximating the serous surfaces of the cecum to the parietal peritoneum. A stiff rubber drainage tube was next inserted into the proximal ileum and fixed with a double purse-string suture. The ileum was now brought out at the lower angle of the rectus incision. The parietal peritoneum was made to hug it snugly by a few catgut sutures, and the abdominal wound was closed in the usual way. The indications for restoring the continuity of the large bowel were improvement of the patient's general condition and the return to normal of the discharge from the excluded large bowel, as shown after repeated chemical, microscopical, or cultured growth examination of irrigation fluids passed through it. This restoration should not be made too early particularly in the ulcerative lesions of the colon. When the surgeon deemed that the large bowel had sufficiently healed and desired to put this organ back into commission, this restoration was readily done by simply cutting out the anus at the lower angle of the rectus incision, closing its end with a purse-string suture, making a lateral anastomosis of ileum to ascending colon or by switching the ileum into the sigmoid. He had never found any difficulty in restoring intestinal continuity. On the contrary, the operation was simple and easy. This paper was based upon the experience he had gained from ten cases so operated. Two were cases of chronic intestinal stasis, with obstructions due to pericolic bands and flexures. Both had greatly improved and were now comparatively well. Three operations were done for the relief of amebic dysentery. All were cured. One was a case of ulcerative colitis with extensive involvement of the sigmoid and rectum. Patient was now in good health. One was a case of extensive obstructive tuberculous colitis. This patient received great relief from the operation and lived in comfort for two months. Three were for late and inoperable malignancies of the rectum. One lived six months, one five months, and the third patient was still living, nine months after operation, was comfortable and in reasonably good health, so there was no mortality in the series.

Dr. Joseph C. Bloodgood of Baltimore discussed the surgery of the colon, with special relation to the methods of resection and suture.

**Adhesion of the Sigmoid.**—Dr. H. A. Royster of Raleigh, N. C., said that sigmoid adhesion was associated with definite symptoms which he believed could be relieved by simple means. Three years ago he directed attention to sigmoid adhesion as a cause of pain in many cases of salpingitis which were attributed to the ovary and other organs. Further experience and observation had convinced him not only of the importance of this adhesion, but of its more widespread interest, so that the whole question had assumed a broader aspect and was coming into consideration in every case of abdominal diagnosis that we had presented to us. Women commonly complained of left-sided pain, but it was not always properly interpreted. The ovary was too often blamed as the

chief offender when, as a matter of fact, there was very little pain associated with ovarian disease. Most often the tube was the source of the pain and usually preceded any ovarian involvement. In a number of instances neither the tube nor ovary was found involved, yet the woman had pain. The particular thing which was characteristic of sigmoid adhesion, as observed clinically, was, first, pain during defecation, and not afterwards. In addition to this, some of the patients described a stoppage at certain points. Constipation was the rule, but in a few cases the condition was associated with mucous diarrhea or a mucous discharge from the bowel. Usually the pain was low down in the left iliac region, but it might be higher up, near the spleen or midway. Most of it was below the anterior spine of the ilium. A typical example of sigmoid adhesion was that of a married woman who had given birth to two or three children. She complained of incessant pain in the left quadrant of the abdomen, and was sent in as a case of tubal disease. Her greatest suffering was on going to stool. She was obstinately constipated. Pelvic examination was negative. Her abdomen was opened and a classic sigmoid adhesion revealed. This was dealt with and the abdomen closed. She had been free from pain now for more than two years. Other similar cases were cited.

Dr. Guy Leroy Hunner of Baltimore said the first of two or three cases he saw of this condition was operated more than once for pelvic and other conditions in the abdomen which might be imagined to be causing the real trouble, and finally these sigmoid adhesions were found and relieved, with recovery of the patient. As regards the etiology, some of these adhesions did not come from the large bowel, but from without to the sigmoid. He found in some of these cases the adhesions ran from the internal inguinal opening over to the large bowel in the shape of fan-like peritoneal adhesions. In other words, the infection had apparently not come from the large bowel at all, but from the lymphatics running into the peritoneal cavity with the broad ligament. He found in some cases chronic urethritis was associated with this condition of left-sided pain, but not all females with chronic urethritis who had pelvic pain had these adhesions.

Dr. Henry T. Byford of Chicago sated that in those cases in which the adhesions were not connected with the sigmoid he thought the pain was usually low down, extended off towards the false pelvis about the iliac region and made it more or less a backache; whereas in the other class of cases the pain extended up along the colon, was apt to extend into the back and be more to the left side.

Dr. James E. Moore of Minneapolis said sigmoid adhesion was a definite surgical entity, and we could relieve it by surgical measures. In a certain number of cases there was a definite symptom which would enable one to make a positive diagnosis from the ordinary examination, and that was a sausage-shaped tumor extending up the left iliac region toward the splenic flexure.

Dr. Walter B. Dorsett of St. Louis said if sigmoid adhesion was due to the colon bacillus or to some other organism, it occurred to him that it would be just as frequent in the male as it was in the female. In dealing with these cases he made the incision in the median line because of the fact that he had had some unpleasant complications in making the incision to the left of the rectus muscle.

Dr. Gordon K. Dickinson of Jersey City spoke of four types of immobilization of the sigmoid. One was the congenital type, where the attachment of the left adnexa to the sigmoid was rather closer than usual and interfered with its function. The second was the inflammatory type from the left adnexa. The third was one in which there were inflammations around the cecoappendix which drew it over to the right and immobilized it, and, fourth, the type described by Dr. Royster. To him he had given a very perfect description of diverticulitis or multiple diverticula of the sigmoid.

Dr. J. Wesley Bovée of Washington, D. C., said when there was infection of the left appendage it was entirely on the peritoneal surface; it would also spread under the peritoneum, and there was infiltration of tissue in the peritoneum which gave rise to adhesions. The one class of cases that gave rise to adhesions was that class in which upon examination he was not sufficiently expert to differentiate between tubal and ovarian disease and sigmoid adhesion. He was not expert enough in many cases to even find the tube or ovary where it had become diseased, for as the result of old infection it was plastered on the wall of the pelvis. If it contained pus, the pus was absorbed. We had a small tube and ovary buried in adhesions and on the surface one could not find them nearly as easily as he could find the round ligament or ureter by bimanual examination in normal cases.

## WESTERN SURGICAL ASSOCIATION.

*Twenty-Second Annual Meeting, Held at Cincinnati, Ohio, December 20 and 21, 1912.*

The President, Dr. L. L. McArthur of Chicago, in the Chair.

**Etiology of Ileal Kink, Pericecal Membrane, and Cecum Mobility.**—Dr. F. Gregory Connell of Oshkosh, Wis., drew the following conclusions: (1) "Anomalies of development offer a rational explanation for these conditions. (2) Coincident or resultant inflammation may cause confusion. (3) Describing the embryological changes in the ileocecal region under the single term 'Rotation' likewise causes confusion. (4) Such changes are: migration, rotation and fixation, one or more of which may be imperfect. (5) The Jackson or pericolic membrane may be due to excessive rotation, delayed migration, early or anomalous fixation. (6) The Lane kink may be due to excessive or anomalous fixation. (7) The cecum mobile is due to an absence of fixation."

**The Fetal Peritoneal Folds of Jonnesco, Treves, and Reid, and Their Probable Relationship to Jackson's Membrane and Lane's Kink.**—Dr. Joseph Rilus Eastman of Indianapolis called attention to the striking similarity of the fetal peritoneal fold described by Jonnesco and Juvara, and designated by them "the parietocolic fold," to the adult peritoneal anomaly described by Jackson as membranous pericolitis and generally known as "Jackson's membrane." Further attention was called to the probable causal relationship between the bloodless fold described by Treves and a pocket-like anomalous peritoneal reflection which was not rare in the adult, and which passed from the mural peritoneum upon the right side quite low down, extending upward and inward over the caput coli and vermiform appendix to be attached to the last two or three inches of the ileum, and to the peritoneum of the caput coli. It formed the boundary of a precolic fossa in which the cecal head and appendix might rest as in a pocket. It was likely that the caput coli with the appendix were, in not rare instances during operations for appendicitis, shelled out of this peritoneal pocket, the peritoneal fold, that is, the bloodless fold of Treves which formed the pocket being looked upon by the operator as an affair of adhesion formation. Moreover, although conceptions of Lane's iliopelvic band, the structure to which was ascribed an important part in the causation of Lane's kink, were somewhat varying, it might be well in discussing the nature and origin of this band to recall that Douglas Reid, of the University of Cambridge, had described under the name of "genitomesenteric fold," a rather common fetal fold of peritoneum which passed from the terminal portion of the ileum into the pelvis. Concerning this genitomesenteric fold, which might be found readily in a surprisingly large percentage of fetuses after the seventh month, or even after birth at term, the question might be raised as to whether it was not related to angulations or gravitations or other deformities of the terminal ileum to which it was attached. The parietocolic fold of Jonnesco and Juvara in most cases arose from the peritoneum at the left or inner side of the ascending colon, passing over the anterior aspect of the ascending colon in an upward slanting direction. It was attached to the parietal peritoneum at the right of the ascending colon. It might adhere to the anterior and lateral aspects of the colon. He ascribed to this fetal fold practically the same relations as were presented by the parietocolic fold when found in the adult. The fold which was described by Douglas Reid and called by him the genitomesenteric fold passed from the mesentery of the last part of the ileum down into the pelvis, being attached below to the genital gland. It would be seen that it had a secondary connection with the ileum and through the peritoneum of the mesoappendix with the appendix itself, a connection which was perhaps responsible for the frequent association of appendicitis and oophoritis. The author had seen this fold in the adult. By lifting the last part of the ileum upward, a thin fold of peritoneum which was quite loose could readily be seen passing from the mesentery of the last part of the ileum over the brim of the pelvis to the region of the ovary. There was no sharp border of this fold upon the right

side. It spreads out on the right into a rather narrow fold of Treves. Reid described this genitomesenteric fold as passing under the appendix, whereas the fold of Treves passed over the caput coli and appendix. In the author's cases the inner or left border of the bloodless fold of Treves had ended in each case below in the genital gland in the fetus at the ovary in the female after birth, and at the internal abdominal ring in the male at term. This was not seen as it was observed by Reid. Certainly it was not noticed as a separate distinct fold, but rather the inner prominent edge of the bloodless fold of Treves, passing from the terminal ileum to the genital gland. It was this genitomesenteric fold of Reid, or the prominent inner border of the fold of Treves as the case might be, which corresponded in its position and attachments to the iliopelvic band of Lane. The relationship between the fetal fold and Lane's band was, perhaps, only hypothetical, but it seemed not unlikely that they were identical. Concerning the origin of Jonnesco's fold, it might be said that several succeeding stages of its formation indicated that adhesions formed between the cecum and parietal peritoneum, while the cecum was still subhepatic. The subsequent descent with torsion or rolling inward upon the long axis drew the mural peritoneum over the ascending colon in a slanting direction.

**The Correlation of Appendicitis, Mucous Colitis and Membranous Pericolitis.**—Dr. A. E. Benjamin of Minneapolis read a paper on this subject in which he drew the following conclusions: (1) "The colon bacillus is a most deadly enemy of the human race. (2) Owing to the dietary habits and the upright posture assumed by man the propagation of the bacillus is favored. (3) The congenital body form and the imperfect development of the large intestine, as well as insufficient support and pressure of clothing, favors visceroptosis and visceroptosis favors stasis. Repeated attacks of colitis in children may terminate in a chronic form of the disease manifested in later life. (4) Intestinal stasis causes a multiplication of colon bacilli within the colon. (5) The weakest portion of the colon, namely, the cecum, owing to its anatomical location, is the natural receptacle for retained feces, mucus, bacilli, and other contents of the bowel. (6) The two fixed points, namely, hepatic and splenic flexures, inhibit fecal circulation, and where there are kinks, resulting stasis occurs. (7) The reverse peristaltic waves and the uphill course of the first part of the colon are prime factors in the production of stasis in the cecum. (8) When stasis and intercolonic tension exists, in the presence of retained infectious microorganisms, the law of osmosis is put in operation and a transmigration of these organisms through the walls of a thinned out colon occurs. (9) There is always a reaction on the part of tissue thus invaded and barriers offered to protect surrounding structures. (10) Without the colon these barriers are manifest in the form of a veil-like membrane radiating from the parietal peritoneum to and over the area of the colon most affected. (11) This membrane may not be placed uniformly over the colon or cecum, but often in an imperfect and crippling manner. (12) The pressure of these bands may cause degeneration and scarring of the intestinal wall with contraction, resulting in thick bands or dense adhesions which produce obstruction and secondary stasis. (13) When these fibers hamper the action of the large gut they are a menace to the health of the individual and must be removed. (14) The appendix is often caught in this veil-like membrane or dense bands with resulting constriction and degeneration of its walls. (15) When the freedom of action of the appendix is thus interfered with, bacteria are retained and further degeneration and infection result. Acute attacks of appendicitis may supervene following chronic symptoms of the disease. (16) A chronic colitis sooner or later may result in membranous pericolitis and demand surgical intervention to relieve an imprisoned or restrained portion of the colon or appendix. The results of such an operation depend to a great extent upon the inauguration of consistent dietary and general hygienic measures following the operation. (17) Button-hole incisions for appendicitis should seldom, if ever, be employed. (18) Surgeons must take a more comprehensive view of diseases of the abdomen, and especially of the right side and cease to focus their attention on the appendix alone. (19) A careful observation must be made of all the abdominal organs at the time of the operation, and a general view taken with a clear understanding of the clinical symptoms and careful investigation of the pathology requiring attention, and with an intelligent interpretation of these our results will be quite satisfactory.

Dr. Van Buren Knott of Sioux City, Iowa, said he had thought that the so-called Jackson membrane was more a congenital anomaly than a pathological entity. He had encountered it many times when the abdomen was opened for any pathological condition, when no symptoms existed which could be attributed to the presence of the membrane.

Dr. W. D. Haines of Cincinnati said there was a definite and known cause for colitis. It was an infection of the intestinal wall, and it was the same as other mucous lined surfaces when they became infected, the difference being chiefly in the mechanics of the part, whether it be the gall-bladder, the appendix, or gut itself. If one was not absolutely sure of the diagnosis before operation, the incision should be sufficiently large to permit one to see and act intelligently.

Dr. Jabez N. Jackson of Kansas City, Mo., said the main thing he had endeavored to force upon the profession was the recognition of a pathological or abnormal condition, whether it be congenital, inflammatory, or what not in its origin, a condition which was found about the right side of the colon in a very definite percentage of the cases, and a condition which was clearly definable. It was a clinical entity which presented an absolutely characteristic train of symptoms.

Dr. W. W. Grant of Denver reported to the Society in Denver a most interesting case in which there was a condition of the appendix without local symptoms other than those referable to the stomach. While examination showed hyperacidity of the stomach, an exploratory operation showed absolutely no disease of the stomach or gall-bladder, but the tip of the appendix was covered with the so-called Jackson membrane, looking exactly as it did in the fetus, except that there was a great deal of congestion and redness of the blood vessels covering the cecum. Removal of the appendix cured this patient in two months.

Dr. Daniel N. Eisendrath of Chicago suggested that cases be watched for the next two years, observations at the operating table made, and follow the cases along and see how much benefit they had derived from the various methods of operation, and how much need there was for any operation in a great many of these conditions. He had made notes in a great many cases of so-called movable cecum, of ptosis of the ascending colon and transverse colon, and he had been following them up. A chart showed contradicted what Dr. Jackson had said, namely, that the Jackson membrane did not form in ptotic colon. This picture showed that the cecum lay between the bladder and the right pelvic wall. Dr. Jackson had pointed out that the pericolic membrane covered the ascending colon down to the cecum. In these cases there was absolutely no symptom referable to the ptotic condition of the colon. The entire ascending colon and cecum were in the condition that had been described as cecum mobile or complete ptosis of the cecum.

Dr. Warren A. Dennis of St. Paul, Minn., thought this question could be definitely settled by means of co-operative work and by making definite records of the conditions found in the various cases. If all would record the actual conditions found in children operated upon, we could determine the relative frequency of this membrane in children. A certain number of cases would be operated on later in life, and some of them would develop this membrane, and perhaps some of them would not, but we could only reach a definite conclusion by having a good many men work together.

**Retrocecal Appendicitis.**—Dr. Jabez N. Jackson of Kansas City, Mo., described four separate anatomical subvarieties of the general postcecal type. (1) The appendix, possessing its usual mesentery, was only distinctive in the fact that it ran upward along the outer side of the colon which overhung and confined it in the limited peritoneal space external to the colon. (2) Another type ran upward external to the colon under cover of the peritoneum of the posterior parietes which formed its investment, usually incomplete, on its posterior circumference, and even though complete not furnishing a mesentery proper. (3) Again, he had found the appendix running up along the external wall of the colon itself and invested by its proper tunic and likewise without mesentery. (4) In the fourth type the appendix ran upward directly behind the colon beneath which it was buried in connective tissue entirely, and had no direct peritoneal investment whatsoever. In the retroperitoneal type we might permit embolic infection of the liver with multiple abscesses entirely beyond any hope of relief by surgical means or otherwise. He would, therefore, emphasize the need of early diagnosis and early removal of the appendix as particularly indicated in this anatomical type of appendix.

Dr. W. W. Grant of Denver stated that in a paper on "Retrocecal Appendicitis," read before the Colorado State Medical Society in 1903, he called attention to a symptom not mentioned by the essayist in speaking of the symp-

tomatology, namely, a tender point two inches above on an intersecting line directed upward from McBurney's point and from the umbilicus. In these cases of post-colonic appendicitis, without preliminary symptoms, one would find this to be the most distinctly tender point. A prompt operation in the class of cases described with drainage through the lumbar region would cure a large proportion of them.

Dr. Walter R. Dorsett of St. Louis said he was particularly interested in Dr. Jackson's classic description of this condition, but mostly in regard to the necessity for lumbar drainage even after we had opened anteriorly. Three such cases had come under his observation. In these he was fortunate enough to make a diagnosis of retrocecal appendicitis and opened, first, through the lumbar region, drained, and then went in afterwards in front and removed the appendix, for the reason that the appendix was very hard. He removed it through a lumbar incision. It was worth while to consider drainage before the ablation of the appendix.

**Gunshot Wounds of the Abdomen.**—Dr. Maurice Kahn of Leadville, Col., stated of 41 cases of gunshot wounds seen in civil practice, 13 (31 per cent.) were of the head, 8 (19 per cent.) of the chest, and 13 (31 per cent.) of the abdomen. He cautioned against dogmatism in asserting that portions of the body distant from the wound of entry were not involved, as remote organs were occasionally injured, and cited a rare case of his own: a boy was accidentally shot with a .22 caliber rifle, the bullet entering the external aspect of the right thigh at its middle third, and death from peritonitis resulted on the fourth day. He maintained that the soft tissues of the abdomen were incapable of deflecting a bullet, hence a bullet must traverse that cavity in the straight line of its projection. On account of the danger of hemorrhage, and the rapid absorption in the upper abdomen, he also combated the universal belief that wounds of the lower abdomen were attended with a higher mortality rate than were those of the upper abdomen. Despite the fact that army statistics showed that conservative treatment was the more successful in war, and that it was possible for a bullet to traverse the abdominal cavity without visceral perforation and he cited one case of his own in which this occurred, nevertheless in every case of penetration of the abdomen by a bullet, multiple perforations of the viscera were to be assumed and prompt surgical exploration demanded. The symptoms usually mentioned were not those of perforation, but were signs of hemorrhage or peritonitis. Given a case with indications of probable involvement of the abdomen one should not wait for symptoms, but should proceed at once with the operation. Needlessly long incisions, evisceration, rough handling of the gut and long exposure were to be condemned; however, much time might be wasted by attempting a thorough search through an insufficient opening; therefore, he always made an opening sufficiently large to permit rapid work regardless of its length. Also, in the presence of a belly full of blood, he turned out intestines abundantly to expedite finding the source of the hemorrhage, which, if profuse, arose from the solid viscera, mesentery, omentum or large vessels, as wounds of the hollow viscera bled but slightly. Trimming the bruised edges of intestinal wounds required time, which might be of great import, and was unnecessary, as the edges could be safely infolded. On account of the tonically contracted bowel, care should be exercised that the bite of the suture was no deeper than was intended. Thorough exploration for distant perforations was urged, as many cases had been lost by neglecting to repair all wounds. The general principles governing drainage in abdominal conditions would determine one's procedure in a given case. When in doubt it was safer to drain. Of 13 cases, 7 were operated upon. Excluding one, which involved the thorax and abdomen, and which died of secondary pulmonary hemorrhage, there were six purely abdominal cases with intestinal perforations operated upon within 8 hours of the accident; 5 recovered, and 1 died, a mortality of 17 per cent.

Dr. W. W. Grant of Denver said in reference to the diagnosis, if we knew the point of entrance of the bullet and its exit, we could tell with some degree of accuracy as to the course it had pursued; but often there was no exit; the bullet was lodged in the body, and under these circumstances and conditions he would suggest that the *x*-ray would locate the bullet, and knowing its entrance, even if we did not know its exit, we would know pretty well what course it had pursued, and this could often be done within an hour or two. It was a fact that every hour, after about four hours, increased the mortality from these wounds without operation. Therefore, operation in every case of wound from a bullet should be undertaken. If there had been no wound of the intestine or stomach the patient would not die from an exploratory operation. The first consideration was hemorrhage, and not extravasation, because it was the hemorrhage that produced shock; it was the hemorrhage that produced immediate death, and not peritonitis, so that the first consideration was to stop the hemorrhage.

(*To be continued.*)

## NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

*Special Meeting Held November 29, 1912.*

Dr. Franklin A. Dorman in the Chair.

**Cyst of the Corpus Luteum Simulating Ectopic Gestation.**—Dr. Franklin A. Dorman reported this case which was of interest because there was with it a story of a mistaken diagnosis. The patient was twenty-four years of age, married, and was first seen on October 25. Her menstruation began at the age of fifteen and occurred every twenty-eight days. Her last menses occurred on August 28. She had one child with instrumental delivery four and a half years ago. Three years ago she had a miscarriage. Nine months ago she was operated upon for chronic appendicitis. At the same time she had a Gillian suspension and a buttonhole suspension for prolapsed ovaries. Six weeks ago she began to have pain in the left lower abdomen, variable but increasing, together with morning vomiting and this had continued during the past four weeks. She was admitted to the hospital on October 25 complaining of severe pain; she then had a temperature of 99.2°, pulse 100, anad respirations 24. The blood count showed leucocytes 18,500 and polymorphonuclears 81 per cent. and lymphocytes 19 per cent. The examination revealed a mass which was very tender in the left fornix with fulness in the cul-de-sac of Douglas. As the uterus was held in place by the suspension operation, it was a difficult matter to determine the degree of enlargement of the uterus. A tentative diagnosis of ectopic gestation was made and operation was done on the following day. There was found a mass on the left side which was presented to the Section. The specimen consisted of a Fallopian tube of rather small caliber and tortuous in outline and it was intimately attached to a ruptured cystic structure about the size of a walnut. This was apparently an ovary, as it could be identified by the presence of a large corpus luteum. The microscopical diagnosis made was chronic salpingitis with a corpus luteum cyst of the ovary. The patient miscarried October 31. The cyst was thin walled and yellow in color. The point of special interest was the severe pain in a cyst of the corpus luteum of pregnancy.

**Large Intraligamentous Hyaline and Cystic Fibroid with Cystic Ovaries.**—Dr. Dorman exhibited this specimen which presented quite a surgical problem because of the position in the broad ligament. The surgical difficulty, however, was less than might have been because the tumor was shelled out beautifully. The patient made an uneventful recovery. The specimen was taken from a patient forty-one years of age.

**The Infant Pulmotor, an Apparatus for Artificial Respiration on Asphyxiated Newly Born Infants.**—Dr. J. Clifton Edgar presented this apparatus which was an adaptation of the Draegen adult pulmotor to cases of asphyxia neonatorum. The pulmotor was designed primarily to induce respiration in persons who had been overcome by noxious gases, the apparently drowned, those overcome by electric shock, or in any case where the respiration had stopped entirely, but where there was still slight heart action. In the case of the infant pulmotor by the aid of a certain mechanism controlled by hand the respirations could be so timed that a given number per minute might be obtained or so that inspiration and expiration of the machine might be timed so as to coincide with the abortive attempt on the part of the newly born infant. The complete apparatus was enclosed in a convenient wooden box, and consisted of a small high pressure cylinder of one liter capacity, which contained oxygen or varying proportions of oxygen and nitrogen, under 150 atmospheric pressures. By a reducing pressure the high pressure was reduced to a constant pressure of about five atmospheres. Attached to this reducing valve was a gauge which indicated the contents of the cylinder. By means of the reduced oxygen pressure two nozzles were put in action, one for suction and one for presssure. The first action was to force oxygen into the lungs at any given pressure, and the second was to empty the lungs of bad air, which latter was not sucked into the machine but was expelled outside. The alternate filling and emptying of the lungs was under the control of the operator. This control was brought about by simply moving a lever on

a dial. It was claimed for the machine that a mixing of the pure and impure air was impossible. In the limited clinical use to which the apparatus had been put it was pointed out by Roth of Lubeck that in the newly born inspiration as a rule was most successfully carried on with a water pressure of from 10 to 15 centimeters and expiration or suction of from 15 to 20. Two important details had to do with holding the tongue forward to prevent occlusion of the glottis and the closing of the esophagus to prevent forcing air into the stomach. The first was provided for by an attachment to the mask holding the tongue forward and the second was prevented by backward pressure on the larynx. A small rubber bag accompanied the machine for demonstration and testing purposes and a set of instructions for operating.

Dr. Franklin A. Dorman said that usually they could get the lungs expanded in these cases of asphyxia neonatorum by manipulation, but only by continued physical exertion and with bad reaction on the vitality of the child. What was presented was a very scientific way of approaching the matter of resuscitation. Every large maternal service should have the apparatus.

**Tuberculosis in Its Relation to Pregnancy, Labor, and the Puerperium.**—Dr. Ralph Waldo Lobenstine presented this communication. He said that he would endeavor to convince his audience that the strain of childbearing exhausted the vitality of the tuberculous subject and in a high percentage of cases brought about an untimely end. He considered the effect upon the pregnant woman of an active tuberculous lesion, the tuberculin reaction during pregnancy, the effect of an active tuberculosis in the parent upon the offspring, and the proper attitude toward lactation. From the figures presented and the opinion of those who might be considered authorities on these subjects, he concluded as follows: (1) Cases with a healed tuberculous focus might proceed through pregnancy, labor, and the puerperium with little or no disturbance. Rapidly repeated pregnancies had a tendency to cause a renewed outbreak. (2) Latent tuberculosis not infrequently became an active tuberculosis under the damaging effects of parturition. (3) Mild cases with slight fever and moderate cough might stand the strain of pregnancy with apparently little damage; on the other hand, many even of these mild cases were aggravated thereby (35 to 60 per cent.). (4) The deleterious effect was seen, without question, in the majority of the more severe cases. In all advanced stages of the disease, the danger was very great, terminating in practically all cases in an early death. (5) The two periods of great danger were (*a*) during labor and (*b*) in the early puerperium. The prolonged muscular exertion of labor, the loss of blood with its attendant exhaustion, the use of anesthesia, and the possibility of renewed toxins being thrown into the system from the placental site were all serious and far-reaching in their results. At this time the tuberculosis might assume a fulminating character and cause death in a surprisingly short period of time. The effect of tuberculosis in the parent on the offspring was shown in the greater tendency to abortion and to miscarriage among tuberculous women. This was particularly noticeable in tuberculosis of the larynx. While it was possible when the disease was stationary for a tuberculous woman to bring forth an apparently healthy child, the majority of these children kept under observation beyond the obstetrical period would show a tendency to develop malnutrition or tuberculosis itself. In the severer grades of tuberculosis the children were usually poorly nourished and underdeveloped at the time of birth. Congenital tuberculosis did occur but only in exceptional instances; however, the best of foreign observers were of the opinion that a good many so-called post-natal infections were in reality cases of intrauterine infection. In the light of recent work on tuberculosis of the placenta this possibility should be carefully weighed. According to Weinberg, 67.9 per cent. of the infants of tuberculous parents, whose mothers died within one year after labor, died, likewise in the first year of life. Of 50 infants born alive, whose mothers died within four weeks of labor, 78.8 died within the first year. If to these early deaths were added the vast army of children who later developed the disease from contact with tuberculous parents, the great toll on health and life due to faulty inheritance and faulty surroundings could be appreciated. Nursing of an infant by a tuberculous woman was a double menace and should never be allowed. Even though the mother seem to be in fairly satisfactory condition, her ultimate recovery was more likely to be retarded if nursing was indulged in. The majority of such children would thrive better on the milk of a wet nurse or on cow's milk properly prepared. In all truly active cases the ideal method was the isolation of the child. The general treatment of these cases resolved itself into practically the same general methods that were employed in non-pregnant women. The difficulties, however, were far greater as these cases were in more need of judicious care and advice. It was difficult to get them to go away from home and difficult to get them admitted to a sanatarium on account of their pregnancy. The obstetrical management of these cases divided itself into four operative procedures: (1) Simple artificial abortion. (2) Artificial abortion followed either immediately or at later date by resection of the Fallopian tubes. (3) Abdominal or vaginal hysterectomy after the removal of the fetus. (4) Artificial abortion followed by excision of the placental area *per vaginam*. During the first three or four months of pregnancy an abortion should be performed, if possible, in all active cases, and the less delay there was the better. In cases with a tuberculous tendency, but with no active lesion, this operation was not justifiable. It was not indicated in cases with healed lesions, providing the patients were in good health. The operation should be performed under strict aseptic precautions and preferably after a preliminary tamponage with 5 per cent. iodoform gauze. All operations performed under these circumstances demanded light and scientifically administered anesthesia. While the therapeutic abortion was so often indicated, the induction of premature labor was not. A consultation was essential before undertaking any one of the operations under consideration. The operation of salpingectomy was now widely urged in all active early mild cases in which the uterus was emptied. By emptying the uterus in these early mild cases the patient's health might be restored and life prolonged many years. If salpingectomy were performed the patient's health would have a better chance of remaining good and the danger of bringing poorly nourished offspring into the world would be removed. Radical interference was the only way of offering these women a fair chance of improvement. Veit from a study of 347 active cases in which abortion alone was performed, had shown that 43.3 per cent. were not helped by it; while Bardleben claimed that 50 per cent. of his active progressing cases died after artificial abortion. In those cases found to be progressing rapidly in the middle trimester or late in pregnancy, no operation would prove of much value. Dr. Lobenstine explained the unsatisfactory results in the severe cases as due to tuberculosis of the decidua or placenta which in the light of recent investigations had been shown to be of more frequent occurrence than was previously believed. Schmorl, Geipel, and Wertheim now asserted that tuberculosis of the placenta occurred in 45 per cent. of tuberculous pregnant women. The vaginal excision of the placental site was a new procedure which, despite the excellent results of its originator, v. Bardeleben, did not appeal to most of them. Abdominal hysterectomy seemed to him the operation of choice; it enabled one to make a more thorough inspection of the appendages, in case these were likewise the seat of disease. Dr. Lobenstine made an urgent plea for more stringent legislation in order to restrict the marriage of the tuberculous and, in the meantime, where the tuberculous married in spite of remonstrance, it was their duty to urge upon them the necessity for the prevention of conception. Knopf believed in vasectomy for all tuberculous male patients and salpingectomy for all tuberculous female patients, whether married or single, who would submit to the operation. He would make this obligatory for all acutely active cases. This attitude was shared by many clinicians who had studied the problem thoroughly and had broken away from the narrow-minded ways of the past. If this applied to tuberculosis, it applied with even greater force in the presence of mixed tuberculosis and syphilis or tuberculosis and alcoholism.

Dr. J. Clifton Edgar said that since Dr. Charles C. Tremley of Saranac Lake had read a paper on this subpect before the Section on Obstetrics and Gynecology three years ago it had been the consensus of opinion that the therapeutic operation would be the issue of the future, not only in the frank cases of tuberculosis but in the latent and so-called cured forms of the disease. Few could understand the attitude of Pinard of Paris, who claimed that certain cases of tuberculosis were improved by pregnancy. During the first few months of pregnancy these women seemed to be improved, but after the fifth or sixth month they seemed to fade away. The best attitude to assume was that of the alarmist from the very beginning. He could not see how pregnancy could better in any way any type of tuberculosis, whether it was latent, cured, or moderately active. The question before them was a difficult one when they considered the people in moderate circumstances and without proper surroundings. Many of

the children of tuberculous mothers appeared to be healthy but did not have the resistance to disease that other children had. In cases of incipient or so-called cured turberculosis, with no tubercle bacilli in the sputum and with no physical signs of the disease, or those even with a small spot, the consideration of the case came down to a question of environment and circumstances. In patients with a tendency to the disease, he believed that it was a dangerous procedure to empty the uterus in every case. If these patients had been allowed to go nearly to delivery, labor should be made as easy as possible. They should be let alone during the first stage of labor, but the second stage should be made as easy as possible; anesthesia should be used and instruments applied. With regard to the care of patients during the puerperium and nursing period, he agreed with what had been said. It should be borne in mind that in many of these cases it was better to cut off pregnancy by two weeks; this gave an easier labor and produced less shock and strain on the woman.

Dr. Herman J. Boldt said that the induction of an abortion on the indication "a tendency to tuberculosis" could not, in his opinion, be considered other than malpractice if he understood correctly the definition of "tendency to." One might say of any person who looked thin and was of slender physique, in whose family there was someone afflicted with tuberculosis, who might appear somewhat below par, that a tendency to tuberculosis existed. If such a person was a woman who was pregnant and whose desire was not to have her child this might be assumed as a reason for the induction of abortion. The induction of abortion was indicated only when the woman had incipient phthisis or phthisis not far advanced, in an active state, and if it was shown that under the influence of pregnancy the pulmonary condition was aggravated. For one's own sake as well as for that of the patient, it was advisable to have this certified to, not only by the family physician but by someone who had made a special study of tuberculosis and who was fitted to give an opinion based on experience from the observation of such patients. Sterilization was justifiable in all such cases. If done the technique should be such as would really assure prevention of conception. The tying of the Fallopian tubes was inadequate; but if the interstitial parts of the tubes were exsected and the uterine wound closed with a continuous suture, the patient retained menstrual function and was absolutely sterilized. Moreover, the operation was readily done by the vaginal route. Hysterectomy was not, in his opinion, indicated. The induction of abortion or of premature labor was contraindicated in all cases where the pregnancy had advanced further than the first half of the period of gestation, when the pulmonary lesion was so far advanced that a marked improvement of the patient, a quiescence of the disease, could not be hoped for. All patients who had had or who might have active pulmonary tuberculosis, accompanied by pregnancy, should be kept under most careful observation and at the first sign of renewed activity of the disease the patient should be advised to have the uterus emptied at the earliest possible moment. Questions of religion should not enter into consideration where human life was involved. To his personal knowledge in one strictly sectarian hospital in Germany, only the medical side was considered.

Dr. S. A. Knopf said that hitherto he had assumed the attitude of non-interference in early and moderately advanced cases of tuberculosis complicated by pregnancy, but he was willing to confess that he was more and more inclined to advocate the emptying of the uterus in all cases where a positive unhealed tuberculous condition existed. In addition to the authorities quoted by the reader of the paper, there were Schottelius and Schaute who stated in a recent article that they had come to the conclusion that, in view of the uncertainty of the prognosis in a tuberculous pregnancy the emptying of the uterus was indicated in every case. Carefully gathered statistics showed that in 75 per cent. of positive cases of tuberculosis the pathological process increased rapidly during pregnancy, and particularly after delivery, to a fatal termination. If after careful counsel with a competent, or, better, two competent consultants for internal diseases and an experienced obstetrician, the diagnosis of pregnancy was certain in a tuberculous woman, the careful and aseptic emptying of the uterus was indicated and was connected virtually with no danger. It went without saying that the ligation of the Fallopian tubes at the same time or soon after was indicated. The reader of the paper stated that 200,000 persons died annually in the United States from tuberculosis, but he did not give any adequate idea of the severity of the problem because he did not include the morbidity of the disease. It has been proven that there were eight times as many tuberculous individuals as were represented by the death rate. If one considered that the majority of this vast number were poor and might become a burden to the community, it certainly seemed timely to stop tuberculous procreation. Prevention was vastly better than interference, and Dr. Knopf said he was willing to take the responsibility before the law and his God for every time he had advised tuberculous individuals not to procreate. The uterus in these cases should never be emptied without the written and sworn consent of the husband and no subsequent sterilization should be resorted to unless the operation had been agreed upon by two competent internists and an obstetrician or gynecologist. The problem presented was an important one and it was regrettable that it was not presented to an audience as large as possible of general practitioners.

## MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting, Held December 23, 1912.*

The President, Dr. Charles Gilmore Kerley, in the Chair.

**Moving Picture Illustrations of Nervous and Mental Diseases.**—Dr. T. H. Weisenburg presented only 5,000 of the 20,000 films originally taken because of the time requirement. He had very little to say because the pictures spoke for themselves. He conceived the idea some five years ago of taking moving pictures for class room work. They enabled him to explain symptoms more easily. He expected to extend the picture taking to the operating room. The pictures illustrated every known form of nervous disease and their clinical symptoms. They also illustrated the methods of making examinations, including the taking of reflexes, the different types of gaits, stature, etc. Among the nervous diseases shown were hemiplegia, diplegia, paralysis agitans, locomotor ataxia, disseminated sclerosis, poliomyelitis, muscular dystrophy, syringomyelia, ataxic paraplegia, cerebellar and other tumors, Jacksonian and general epilepsy, spasms and tics in various parts of the body, Huntington's and Sydenham's chorea, astasia abasia, and hysterical states. Among the insanities shown were dementia præcox, which was illustrated by twenty-six cases, manic depressive insanity, chronic mania, paranoid states, paresis, melancholia, etc. Dr. Weisenburg believed that the work of the moving picture in medicine was limitless. It was an expensive method, but the expense was more than compensated for in the results obtained.

## Books Received.

*The* Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Physiothérapie Du Lupus. By Dr. L. Dekeyser. 121 pages; illustrated; paper. A. Maloine, Publisher, Paris.

Taschenbuch der Therapie. By Dr. M. T. Schnirer. 476 pages; cloth; price 2 M. Curt Kabitzsch, Publisher, Wurzburg.

Surgery of the Brain and Spinal Cord. By Prof. Fedor Krause, M.D. English Adaptation by Dr. Max Thorek. Vol. III. 1201 pages; illustrated; price $7.00. Rebman Company, Publishers, New York.

Diseases of the Mouth. By Prof. Dr. F. Zinsser. Translated and edited by John Bethune Stein, M.D. 269 pages; with 52 colored and 21 black and white illustrations; cloth; price $7.00. Rebman Company, Publishers, New York.

Aufgaben der Glaukombehandlung unter der Kontrolle des Schiotzschen Tonometers. By Prof. V. Hippel. 46 pages; paper; price, 1.20 M. Carl Marhold, Publisher, Halle.

Beiträge zur Beurteilung und Behandlung des Konkomitirenden Schielens. By Gustav Caesar. 41 pages; paper; price, 1.50 M. Carl Marhold, Publisher, Halle.

Hundert Totalexstirpationen bei Myoma Uteri Ohne Todesfald. By Dr. S. Flatau. 92 pages; paper; price, 2.40 M. S. Karger, Publisher, Berlin.

Beiträge zur klinik und Histopathologie der Gutartigen Hautepitheliome. By Priv. Doz. Dr. Walter Freiboes. 95 pages; illustrated; paper; price, 8 M. S. Karger, Publisher, Berlin.

## Therapeutic Hints.

**Antipyrine by Rectal Injection.**—A. Guérin notes that Montenius has recommended the use of antipyrine administered in the form of a small rectal injection in the treatment of infantile convulsions and vomiting. In these cases the dose is 25 to 50 centigrams dissolved in 15 grams of water. Guyon and Guiard state that when administered in this manner, with the addition of a small dose of opium, antipyrine acts as a marked sedative to the bladder, especially in prostatics. Mastboom employs antipyrine in the treatment of pelvic neuralgias, dysmenorrhea, and coccygodynia, according to the following formula:

℞ Cocaine hydrochloride, 0.10 gram.
Antipyrine, 10 grams.
Distilled water, 30 grams.

Of this solution one teaspoonful is to be administered in the form of an enema.—*Journal de Médecine de Bordeaux.*

**The Palliative Treatment of Cancer of the Esophagus.**—P. Sée details the following treatment as recommended in a recent volume by J. Thomas. The dysphagia is to be combated by the use of the following pastils:

℞ Cocaine hydrochloride, 0.0025 gram.
Morphine hydrochloride, 0.005 gram.
Antipyrine, 0.10 gram.
Sugar, 0.30 gram.

One or two of these pastils should be taken before each meal.

As an alternative prescription the following is recommended:

℞ Dionine hydrochloride,
Codeine hydrochloride, of each, 0.10 gram.
Cocaine hydrochloride, 0.25 gram.
Ammonium valerianate,
Bitter almond water, of each, 7.50 grams.

Of this solution, 15 drops should be taken three or four times a day.

Certain authors, as Liebermeister, advise the use of peroxide of hydrogen, in a one per cent. solution, of which the patient should take a mouthful every hour. The object is to cleanse the surface of the cancerous lesion and to increase the permeability of the stricture. The dyspnea which is symptomatic of pressure upon the trachea may be relieved by the use of ether, which may be administered by inhalation or by ingestion in the form of a syrup or in pearls; by the use of oxycamphor, in doses of 20 drops of a 50 per cent. solution in alcohol five times a day, or by the use of inhalations of oxygen.—*Revue de Thérapeutique.*

**The Prescribing of Creosote Carbonate.**—C. A. Ewald and A. Heffter recommend the following modes of prescribing creosote carbonate:

℞ Creosoti carbonat., 20 grams.
Vini tokayensis, ad 200 grams.
M. et Sig. One tablespoonful t.i.d.

℞ Creosoti carbonat., 15 grams.
Olei jecoris aselli, ad 150 grams.
M. et Sig. One tablespoonful t.i.d.

℞ Creosoti carbonat., 30 grams.
Syr. altheæ,
Cognac, āā, 15 grams.
M. et Sig. To be well shaken; 10 drops, t.i.d.; dose to be gradually increased.

This drug may also be taken pure, followed by milk, or mixed with fruit jam.

"Handbuch der allgemeinen und speziellen Arzneiverordnungslehre," 1911.

## Miscellany.

**Insanity and Epilepsy in Ancient Times.**—R. Jones notes that insanity was familiar to the Egyptians, whose mentally afflicted were taken to the Egyptian temples, where they were treated by the priests with incantations and sacrifices. Traditional medical knowledge in regard to the insane is said to have been carefully preserved in India. Among the Greeks, Æsclepiades constituted an hereditary order of priesthood, who were supposed to exercise curative powers over insanity; and there were Greek laws made 500 B.C. defining those lunatics who had to be confined. The Romans in their laws guarded the insane as well as their estates. Some of the earliest authentic cases of insanity, as well as of epilepsy, are related at considerable length in Holy Writ; for instance, the insanity of King Nebuchadnezzar, and also his recovery, after which it is recorded he was replaced as King upon the throne of Babylon. The history of King Saul, 1000 B.C., also relates his insanity, and there are several descriptions of epilepsy, the most typical being the only child, who was also a lunatic, for he "suddenly crieth out and foameth at the mouth and gnasheth his teeth," and "oftentimes he falleth into the fire and oft into the water." The ancients not infrequently ascribed epilepsy to the malice of demons, or to the anger of offended deities. If a person was seized with epilepsy in the forum, the Romans considered it an ill omen, the meeting was dissolved, and all public business was suspended for that day. Hence the disease was called *morbus comitialis. Morbus qui sputatur* was another of its names, because those present were accustomed to spit upon the epileptic, or into their bosoms, either to express their abomination and loathing, or to avert the evil omen.—*The Practitioner*, December, 1912.

**The Madness of Kings.**—The recent death of the aged Regent of Bavaria, and with it the reopening of the whole painful story of this ill-fated house, raises questions of peculiar interest in connection with the psychiatry of royal personages. It would appear at first sight that, if the moral and intellectual qualities of a sovereign can add to the enrichment and glory of a nation, the contrary should also hold good. It is remarkable to note, however, how little dependent the evolution of a nation really is upon the mental or physical health of its monarch. Moreover, the history of the House of Bavaria shows that a madman clothed in purple can on occasion be an excellent head of the State. The outstanding cases of insanity in reigning monarchs are not numerous. Perhaps one of the earliest to which historical reference is made, is that of Nebuchadnezzar, King of Babylon, who suffered from lycanthropy, a form of insanity of comparative frequency in antiquity as well as in the Middle Ages. Beyond being afflicted with jealousy amounting almost to monomania, there is no indication that Saul, King of Israel, was insane. More recently Peter III of Russia, grandson of two great kings—Peter I on the maternal side, and Charles XII of Sweden—was a degenerate in the full meaning of the term. Paul I of Russia, his son, was sickly, weak, and epileptic from birth. He it was who proposed that the sovereigns of Europe should settle their differences by mortal combat. Although he imperiled the country by his extravagance and eccentric habits, the pathological history of Paul is interesting in that he was the superior of his father. —*British Medical Journal*, January 4, 1913.

### SOME NEWER PROBLEMS AND SOME NEWER PHASES OF THE ANTI-TUBERCULOSIS WARFARE IN THE UNITED STATES.*

By S. ADOLPHUS KNOPF, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE, DEPARTMENT OF PHTHISIOTHERAPY, OF THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

ABOUT two decades ago, when the sanatorium movement in Germany and in the United States received its greatest impetus from the results obtained by Dettweiler, a pupil of Brehmer, and by Trudeau, many believed that the problem would be solved if we could get enough sanatoria to treat the early cases, retain them there six months or a year, then send them out again to the ordinary walks of life, making room for new ones.

Future cases of tuberculosis we thought we could prevent from developing, or at least diminish in number, by our knowledge of the behavior of the tubercle bacillus as the direct agent of infection and propagation. Effective sanitary measures to prohibit the spread of tuberculosis by indiscriminate expectoration we thought the most essential measure. For a number of years after Koch's declaration at the London Congress in 1901, the transmission of tuberculosis by the bovine type of the bacillus was considered improbable, or at least of minor importance, until new evidence, brought forward by various investigators, particularly English and American[1], proved beyond a shadow of doubt that tuberculosis is caused in childhood in from 5 to 10 per cent. of cases by the ingestion of milk from tuberculous cows. New bovine laws were created or the older ones more rigorously enforced, yet as far as the United States is concerned the peculiar situation arising from the absence of a federal department of health and the lack of uniformity or total absence of bovine laws in some of the States of the Union, must be held responsible for the great prevalence of tuberculosis in childhood due to the bovine type of the bacillus. Thus, one of the first newer problems, or let me rather say, most important problems, is to do away with this source of tuberculosis in childhood. How bovine tuberculosis can be successfully combated among our milch cows is a topic with which you expert sanitarians are familiar and your experience in this work exceeds mine many times, but I know you will agree with me that without a federal department of health, without uniform bovine laws and federal authority to enforce them we are powerless.

*Read before the American Public Health Association at its annual meeting in Washington, September 19, 1912.

Milk inspection, pasteurization, the grading of milk, and milk standards, are subjects likewise so often and well discussed in this society that I do not feel I can add anything new, except to express my belief that with our present knowledge pasteurization is a necessity for protecting the general milk supply, particularly of a large city, from the germs of tuberculosis and other infectious diseases.

There is, however, one feature which seems to me deserves mentioning under new problems. I refer to the likelihood of infection from tubercle bacilli of the bovine type in butter. Investigations in this[2] and foreign countries by competent men have shown a rather frequent occurrence of tubercle bacilli in butter, and while it may be difficult to trace infections arising from this source, the presence of the tubercle bacilli in any article of food substance demands serious attention. The relatively small number of bacilli ingested with butter may not be injurious when not repeated, but Hess has shown that partaking daily of milk containing small numbers of tubercle bacilli may cause infection when the same quantity taken in one dose failed to produce tuberculosis.[3]

Because it is exceedingly difficult to examine all the specimens of butter coming to the market from sources where milk inspection is lax, obligatory sterilization of all cream destined for butter production, as is the law in Denmark, would seem the only method to do away with this source of infection from bovine tuberculosis. Here again we see the great and urgent need of a Federal Department of Health to protect the public.

The marriage of consumptives and whether they shall be allowed to procreate, is a problem which has received some serious attention of late. It is a subject large and important enough to be treated by itself, so I will now merely express my personal opinion on the subject as I did in a recent communication, entitled, "Primary Sources of Tuberculous Infection and Their Relation to Eugenics."[4]

Our social reformers tell us: The first thing you physicians must do is to prevent the tuberculous from marrying. This is more easily said than done. Certainly we know there are a number of States in which a certificate of health is demanded before a license is issued, and recently some brave clergymen, foremost among them the Very Rev. Walter Taylor Summer, of the Protestant Episcopal Cathedral of St. Peter and Paul of Chicago, have declared that they would bar all marriages unless the couples were armed with a physician's certificate saying that they have no trace of insanity, tuberculosis, or other communicable disease. If I have the quotation correct, I would object to the wording of this declaration, for, if the reverend gentleman really means that he will not marry anyone who has even a trace of tuberculosis, he will have a chance of perform-

ing the ceremony relatively rarely. What the old German Geheimrath said many years ago still holds good. I refer to the often quoted words, "Am Ende haben wir alle ein bischen Tuberkulose," which might be freely translated: taking all things in consideration, perhaps every one of us has or has had at some time or other a little tuberculosis.

A mere trace of tuberculosis should not bar any one from marrying and propagating, but with a distinctive lesion, likely to become acute at any moment, or with a very strong predisposition, marriage and procreation should be deferred until the prospective husband or wife is cured. I cannot speak for the experience of others, but as for myself in years of consultation practice, I have had occasion to prohibit marriage a good many times. Sometimes, those who had sought my advice obeyed it, more frequently they did not, and I have come now to the firm conviction that neither State law, clergymen's protest, nor physisian's advice will prevent people from coming together as husband and wife if they want to. I grant that there are exceptions but these exceptions are few.

A somewhat easier task is it when we are confronted with a tuberculous married man or woman whom we desire to convince that as long as he or she is acutely ill with the affliction there must be no children. Such advice the average tuberculous patient is willing to take, but obviously failures are frequent.

It would seem that the time had come for dealing more radically and energetically with this phase of the tuberculosis problem. I plead for vasectomy for all tuberculous male patients who are willing to submit to this operation. I should make this operation obligatory for any one who is acutely tuberculous and insists upon marrying. I would insist upon the ligation of the Fallopian tubes for all female patients in the same situation. I would teach even slightly affected tuberculous parents or married people, not only all the details of prophylaxis so that they may not infect each other, their children, or others, but should make it also a sacred duty to teach them how not to procreate while either one of them is acutely afflicted with the disease. To this end I should go so far as to urge that parents, even when they feel themselves apparently well and strong and recovered from a tuberculous lesion, not to decide on having a child without both submitting themselves to a careful physical examination. Only when found in really good health, as a result of a careful examination by a competent practitioner, should they feel that they have a right to procreate.

My studies in tuberculosis have also taught me another interesting fact which will justify the legitimate prevention of conception in tuberculous parents and the too numerous children to parents inclined to tuberculosis. In taking the history of tuberculous patients I have made it a practice for years always to ascertain the size of the family from which the individual comes and whether he was the first, second, third, fourth, fifth, etc., born of the family. This careful history taking has revealed the fact that the great majority of tuberculous individuals coming from large families were the younger ones. It is nearly always the later born who contract tuberculosis.

There is no doubt in my mind that perhaps the age of the father, but most frequently the system of the mother worn out by repeated pregnancies, has contributed to the physiological poverty of that later born child. The child comes to the world handicapped physiologically. In many instances when the family, because of the number of children, has been reduced to a state of relative poverty, the later born children cannot receive, or have not received either the good care or the good food which was given to the first born at a time when there were not so many mouths to feed. This condition might be considered the sociological reason of the child's predisposition to tuberculosis, added to the physiological causes above described. I have in my records a number of such later born individuals who had become tuberculous in adult life when there was no tuberculosis in their family, but the personal history revealed nearly always a state of health below par from early childhood, and the sociological study of the family a relative poverty.

It would not do, before an audience of this kind, to deny the possibility of direct bacillary transmission through the placenta. These cases are rare, it is true, but they occur, and they occur perhaps more frequently than our statistics seem to indicate.

Recognizing the physiological poverty which a tuberculous parent transmits to the offspring, the economical disadvantage of large families of the poor, the possibility of direct bacillary transmission and the almost certain post-natal infection of tuberculosis from close contact of the child with its tuberculous parent during the early years of life, who is there who would venture to say that the prevention of conception under such circumstances is not a sacred duty?

Concerning another phase of the problem under discussion, that is to say the advisability of emptying the pregnant uterus of a tuberculous woman, each case must be judged according to its own merits. Heretofore I have assumed the attitude of non-interference in early or very moderately advanced tuberculous cases of pregnancy; but I am willing to confess that I am more and more inclined to the emptying of the uterus in all cases where a positive unhealed tuberculous condition exists. I do not stand alone in this seemingly radical attitude. Schottelius and Schaute, in a recent very instructive article on "Abortus artificialis und Tubensterilisation wegen Lungentuberkulose" (Beiträge z. Klinik d. Tub., Band 20, Heft 2), have come to the conclusion that in view of the uncertainty of the prognosis in a tuberculous pregnancy the emptying of the uterus is indicated in every case. Carefully gathered statistics show that in 75 per cent. of positive cases of tuberculosis the pathological process increases rapidly during pregnancy, and particularly after delivery, toward a fatal termination. When, after careful counsel with a competent consultant for internal diseases and an experienced obstetrician or gynecologist, the diagnosis of tuberculosis and pregnancy is certain, the careful and aseptic emptying of the uterus by an expert is virtually connected with no danger. The non-interference means a mortality of 75 per cent. of the mothers and the birth of a tuberculous or predisposed child. It goes without saying that in the majority of these cases the ligation of the Fallopian tubes at the same time or soon thereafter to avoid further pregnancies is indicated.

Prevention of a tuberculous conception, the limitation of children in a tuberculous family, the emptying of the uterus of a tuberculous mother, otherwise doomed if not to an early death to prolonged invalidism, the prevention of tuberculous or predisposed children coming to the world not only handicapped by disease but also by poverty and want

and sure to become a burden to the community, is not race suicide but race preservation.

Until such a time as the radical procedures which I have just outlined will become universal we must have maternity sanatoria where we must isolate and treat hygienically and dietetically all such cases in which prevention and the emptying of the uterus has been neglected. In such maternity sanatoria the mother and her offspring should be treated at least six months before and six months after childbirth.

All children under five years of age who react to the von Pirquet test have, as a rule, a more or less active tuberculous process. In these little ones there has not yet been time to produce an absolute latency of the contracted infection. The von Pirquet test is absolutely inoffensive and I suggest to sanitarians and particularly to lawmakers who have the condition of the nation's health at heart, to make this test obligatory for every child at the ages of two, three, and four. I predict that this measure, which reveals a diagnosis of tuberculosis often difficult to make in children by mere physical means, if followed up by immediate and effective treatment, will prove one of the most successful features in our endeavors to combat tuberculosis.

For the benefit of those who may possibly object to this seemingly radical procedure, I will merely state that the von Pirquet test for tuberculosis rivals, if it does not surpass, the vaccination for smallpox in simplicity and inoffensiveness, and surely the parent who consents to have his child vaccinated for smallpox will not object to an equally simple procedure as a means of saving his child from becoming a victim to tuberculosis.

Open-air schools for tuberculous and predisposed children cannot really be considered a new phase of the antituberculosis warfare. On the other hand, those of us who know the relative scarcity of such open-air schools and who know the invaluable benefits which can be derived therefrom, must wonder why open-air instruction is limited to the few classes in primary schools. I feel so keenly on this one phase of the tuberculosis problem that I have made it the subject of an entire paper which I intend to read before the Congress on Hygiene and Demography which will convene next week in this city.

The equipment of these open-air schools, the cost of feeding, medical supervision, etc., have been so often described that I will not enter into consideration of these subjects; suffice it to say that it pays in the end in health, happiness, and economic gain to take care of these children at the right time and in the right place.

Besides the two types of outdoor instruction (outdoor classes in regular school buildings for the predisposed and outdoor schools for those afflicted with open tuberculosis), there should be that type of schools which are known in Germany as "Waldschulen" (schools in the forest or woods). They are, of course, mainly feasible in summer, but will be of inestimable benefit to the nervous, anemic, scrofulous, or poorly nourished children, all of them strongly predisposed to tuberculosis. To possess a system of such Waldschulen or vacation schools should be the ambition of every city. All these types of schools should be multiplied manifold. I go so far as to say if we really mean to wipe out tuberculosis among the coming generation, open-air schools and open-air instructions should be the rule, indoor schools and indoor instructions the exception. If, as has been proven, when the child handicapped by so serious a disease as tuberculosis, anemia, or scrofulosis is instructed in the open air, it not only holds its own but often does better work than the healthy child raised and instructed indoors, what may we not hope for from outdoor instruction given to the child throughout its school career? And in school career I include a kindergarten course. Because this latter institution rarely has a medical inspection unless it is attached to a public school where the school physician is on guard, it is to my mind a fruitful source of the propagation of infectious diseases. Most frequent of these are the mysterious colds which the little ones bring home and which upon investigation it is shown that all the children have. I am convinced that the open-air kindergarten would do away not only with these so-called colds (which are infections), but would also diminish the number of other infectious diseases children are so prone to.

I am very glad to be able to state here that according to the latest statistics kindly transmitted to me by Dr. Farrand, we have now in the United States 200 open-air schools. While this constant growth is gratifying in the extreme, the number of open-air schools must be many times multiplied in order to accommodate the 600,000 school children in this country who are afflicted with tuberculosis.

The city of Boston seems to be particularly energetic regarding open-air instructions. Its School Committee passed last November the following resolutions:

"Ordered, That the Schoolhouse Commission be requested, so far as feasible, to provide that all rooms in new school buildings shall, on one side at least, open wholly from floor to ceiling to the outer air, in order that during warm weather, at least, the pupils may have as much fresh air as possible."

And now a word about instruction in the open air in higher grades, that is to say, in high schools and colleges. I am aware, of course, that a number of branches in the curriculum of the high schools and colleges cannot be taught outdoors or in an open-air class, but many branches can, and I know from personal experience and from the report of army surgeons in Germany that the recitation and singing in the open air is most conducive to health, the development of sound lungs, and a well-formed chest.

Let instruction in the open air be carried out more universally in high schools and colleges for men and women whenever feasible as well as in primary schools, and I guarantee a stronger and better race physically within a decade, with no intellectual impairment whatsoever. I go even so far as to venture the satement that, if studying mostly in the open air makes it possible for the tuberculous child to accomplish as much and more in shorter hours and shorter sessions, the hours and sessions for the normal pupil of the primary school, high school, and college may also be shortened by this hygienic mode of studying and teaching.

To exclude young children and undeveloped children from the burdens of wage-earning industries.

To forbid employment of all children and youth in industries which menace life, health, and morals.

To limit the hours, forbid night work, and otherwise guard the conditions of children and youth who may be employed.

To promote the efforts of the public schools to meet the recognized needs of an industrial civilization.

These are the aims of the National Child Labor Committee as set forth in a recent announcement. Need I say that unless these conditions are realized in all our States, tuberculosis in childhood and adult life will never be eradicated from our midst?

Read the latest Child Labor Bulletin of August, 1912, published by the National Child Labor Committee, 105 East Twenty-second street, New York, and you will be amazed at the diversity of laws concerning child labor in the various States. How inefficient, how little protective, and even how dangerous they are in some! I cannot too strongly urge all those interested (and everyone should be), particularly our statesmen, to work for the universal adoption of a uniform child labor law, such as is so ably outlined by Mr. Lovejoy in the abovementioned bulletin, and which was adopted at the twenty-first annual meeting of the National Conference of Commissioners on Uniform State Laws (August 25, 26, 1911).

The examination of employees in offices, factories, and workshops is not an entirely new feature in the anti-tuberculosis crusade, and I mention it simply because it is as yet far from being a universal practice. If every employer of a large body of men could only realize what it means morally and even financially to all concerned to have his employees examined for tuberculosis and, when found afflicted, treated and cared for, he would soon follow the example of the few employers who are now doing this life-saving work. It is interesting to note here that one of our greatest life insurance companies—the Metropolitan Life Insurance Co.—has gone so far as to establish on Mount McGregor near Saratoga a special sanatorium for its tuberculous employees. The report of this company's success as a business corporation would certainly show that the unusual care for the welfare of its employees and the consequently increased efficiency of the employees pays in the end.

In a very interesting address recently delivered before the Life Underwriters Association of Canada, Mr. Haley Fiske, vice-president of the Metropolitan Life Insurance Co., very pointedly speaks of the immeasurable value of welfare work for the employees of insurance companies and other corporations with a view to fighting tuberculosis and of a notable victory which was obtained by the Metropolitan Life Insurance Co. in acquiring the legal right for the directors of any insurance company to establish a sanatorium for its tuberculous employees. There was a question of an insurance company having the legal right to spend money for the care of sick employees. To quote Mr. Fiske: "The Superintendent of Insurance, while sympathetic with the enterprise, doubted the power of the corporation to undertake the establishment of such a sanatorium. The question went to the Supreme Court of the State of New York; the decision is emphatic and comprehensive. The Court said:

"The duties of the employer to the employee have been enlarged in recent years, and are not merely those of the purchaser of the employee's time and service for money. The enlightened spirit of the age, based upon the experience of the past, has thrown upon the employer other duties, which involve a proper regard for the comfort, health, safety, and well-being of the employee. * * * It is well within the corporate power to assume, as it has done, the care and treatment of such of its employees as are afflicted with tuberculosis. And unless it is shown to be wasteful of the company's money and unproductive of beneficial results, the practice may stand as well within the scope of the business. The reasonable care of its employees, according to the enlightened sentiment of the age and community, is a duty resting upon it, and the proper discharge of that duty is merely transacting the business of the corporation."

Mr. Fiske continues: "And the court held that such care is not a gratuity, but is regarded as additional compensation. Thus, not only every insurance company, but every corporation, now has the duty imposed upon it to take reasonable care of its sick employees. Not the least service performed by the company has been the obtaining of this decision. The judgment has the support of public opinion. We hope our example in the care of agents will be followed not only by every company represented at this convention, but by every corporation employing labor. The directors have the power and have imposed upon them the duty to use the money of the policyholders and stockholders to care for the employees."

The one suggestion I would wish to make regarding this subject is that where employers alone may not be able to undertake preventive and curative tuberculosis work, employers and employees should unite in a mutual enterprise to insure the employee at least against tuberculosis. Since our political situation makes it seemingly impossible, for the time being, to have anything in the line of a national insurance act such as England is now blessed with, and which marks the beginning of a new era in the campaign against tuberculosis in that country, we must be satisfied with voluntary schemes in the same direction which are feasible at this time.

How this may be done has been very ably outlined by Lee K. Frankel, Ph.D., an authority on life insurance and welfare work of employees, and now assistant secretary of the Metropolitan Life Insurance Company. In his very admirable paper on "Insurance Against Tuberculosis," read before the Sixth Annual Meeting of the National Association for the Study and Prevention of Tuberculosis, in May, 1910, Dr. Frankel says:

"Existing agencies, such as labor unions, fraternal orders, establishment funds, and insurance companies can materially enlarge their present sphere of activities by adding to the sick or death benefits which they give special treatment for consumptives, either through physicians, nurses, or in sanatoria. Whether cash benefits can be given during invalidity is a question of obtaining a morbidity experience, and the ability of the members of policyholders to meet the necessary charges. In addition, any of the above-mentioned agencies may cooperate with antituberculosis associations in the United States, or on their own initiative may undertake a campaign of education to instruct their constituencies regarding the care and prevention of tuberculosis.

"Sickness insurance even on voluntary lines has had but very limited development in the United States, aside from sporadic efforts made by labor unions, fraternal orders, and mutual benefit societies connected with industrial establishments. Any concerted and comprehensive attempt to introduce sickness insurance is as yet unknown. Any such effort on the part of a municipality, such as had been developed in Leipzig, Dresden, and Vienna, has not even been thought of in the United States. It is true that the splendid development

in these cities is primarily due to the fact that the majority of members of the sickness societies are required by law to be insured. It may be assumed, however, in view of the enlightened public sentiment developing in the United States, and the efforts that are being made on all sides to fight tuberculosis, that municipalities and towns might organize similar insurance societies either against sickness generally or tuberculosis in particular. There are reasons to believe that cities, through taxation, might accomplish the same results as those obtained in Leipzig and Dresden. The right of a municipality to tax its citizens is not denied. It is not stretching the imagination too far to suppose that a municipality might impose a tax upon its citizens, which tax should be used specifically for the cure of sufferers from tuberculosis, and to carry out preventive measures for the eradication of the disease. Such a tax might be imposed on the basis of wages, and be apportioned among employers and employees on the assumption that industry to some extent is responsible for the spread of tuberculosis. The taxes thus collected might be set aside in a special fund to be administered by a board of directors made up of representatives of labor and capital, similar to the organization of the Leipzig sickness society. The problem of the care, treatment, cure, and prevention of tuberculosis would be placed in the hands of the board of directors."

Dr. Frankel, in mentioning the fact that these same schemes, when proposed thirty years ago in Europe, were thought visionary, yet to-day they are accepted without cavil and are in working operation in many countries with the approval of the government, employers and employees, then goes on to say:

"The day must come when these insurance schemes will receive recognition in the United States. The day has gone by when social problems may be considered purely from the standpoint of philanthropy. It is contrary to an orderly scheme of things to permit individuals to work under evil conditions, to receive insufficient wages, to subject themselves to disease, and to expect that they shall be satisfied, when they suffer from accident or disease, to receive as a privilege the dole which charity or philanthropy is permitted to hand to them. Germany realizes that the State has distinct obligations toward its citizens. Not the least of these is protection against the risks of life and health incidental to our complex industrial development. It is realized that the workingman alone cannot protect himself against the contingencies of life, particularly against sickness, accident, old age, and unemployment, and that opportunity must be given to him, through some insurance plan, to realize that these contingencies, when they arise, will not deprive him of the means of livelihood. Tuberculosis as a social disease must be considered as one of these contingencies. As a social disease it is recognized that its causes in many instances are obscure; that its effects are far-reaching and affect not only the individual, but the community.

"That it is possible to devise an insurance scheme to meet the exigencies arising from the results of the disease there can be no doubt. Of more importance, however, is the conception that in such a scheme there shall be the opportunity to prevent tuberculosis. Precisely what system may be finally adopted in the United States is still problematic. That the subject is worthy of the consideration of the best minds and the best thought goes without saying."

Although insurance against tuberculosis has not yet been effected by any of the United States life insurance companies, to the credit of the officers of a number of these companies it must be said that they are doing invaluable work in the prevention and cure of tuberculosis among their policyholders by a most efficient educational campaign. The Postal Life Insurance Company of New York even grants periodic examination to their policyholders, as stated in Dr. Eugene L. Fisk's admirable address on "The Physical Welfare of Policy-Holders and What Life Insurance Companies Can Do to Increase It."[5]

The Equitable Life Assurance Society of the United States publishes quarterly an interesting magazine under the name "The Human Factor." Its mission is to serve the officers, employees, and policyholders of the Equitable company and humanity in general by stimulating interest and action in the conservation of life and of life insurance. It is also designed to supply an attractive and instructive medium through which the members present and prospective may keep in touch with the management and with the progress of the society. The same company has an admirable Department of "Conservation" under the directorship of Conservation Commissioner E. E. Rittenhouse.

The Metropolitan Life Insurance Company, because it cannot yet take care of its tuberculous policyholders in its own sanatorium, furnishes cards to all policyholders to forward to the district office in case of sickness. Let me quote again regarding this valuable work from Mr. Haley Fiske's above mentioned address: "The agents, on their calls for premiums, look out for cases of sickness. The nurses visit the office, receive the cards, interview the agents and calls are promptly made. First aid is furnished, the patient is made comfortable, and where necessary the family physician is called, if there is one, or a dispensary or public physician interested where there is no ability to employ a doctor. The nurse then places herself under the direction of the physician and calls as often and stays as long as necessary. Sometimes a call or two suffices; but the number of calls upon a patient has been known to be nearly one hundred. No charge is made, no deduction made from claims. About a million visits are made a year, in about 1,100 cities and towns, at a cost of about half a million of dollars. The nurses employed are, whenever possible, those belonging to local associations. Where associations are not available, the company employs its own nurses. Tuberculosis, pneumonia, bronchitis, influenza, typhoid fever and among children, measles, diphtheria, and paralysis are the principal diseases treated." All these diseases predispose strongly to tuberculosis, and it must be obvious that this is most efficient anti-tuberculosis work. Its value is doubly enhanced by free distribution of the appropriate anti-tuberculosis literature issued by the company. Thus, for example, an illustrated pamphlet has been circulated printed in ten languages, to the number of four and a half million copies and entitled "War Upon Consumption." A supplementary pamphlet containing a list of tuberculosis sanatoria, hospitals, dispensaries, classes, and associations in the United States and Canada, was prepared and circulated in the hope that many sufferers would be directed to places of treatment. Another pamphlet followed, entitled "Directions for Living and Sleeping in the Open Air." It contained directions for making cheap shacks for

roofs, porches, and open spaces, and for window-tents in rooms, with illustrations.

To the student of the causes of tuberculosis as a disease of the masses, the housing of the masses will always be of greatest import. It has always seemed to me that the tuberculosis problem cannot be solved without improving the housing conditions of the poor and the moderately poor, and so I feel that among the newer factors which will be helpful in the solution of the tuberculosis problem in the United States I must mention the invaluable work of the National Housing Association which was founded in New York City a little over a year ago with Mr. Rovert W. De Forest, the president of the New York Charity Organization Society, as president; Mr. John M. Glen, director of the Sage Foundation, as treasurer, and Mr. Lawrence Veiller, former deputy tenement house commissioner, as director. The following are the objects of the association, which speak for themselves:

1. To improve housing conditions, both urban and suburban, in every practicable way.

2. To bring home to each community the importance of right housing conditions and the consequences of bad ones.

3. To study in various cities the causes of the drift of the population into the cities and the methods by which the population may be distributed over larger areas.

4. To encourage the formation of improved housing associations where they do not exist, and to aid in the work of all such associations by advice and direction.

5. To act as a clearing house of information for such agencies, and to furnish advice and suggestions to those interested in housing reform, and generally to promote popular interest in the subject.

6. To aid in the enactment and enforcement of laws that will (a) prevent the erection of unfit types of dwellings; (b) encourage the erection of proper ones; (c) secure their proper maintenance and management; (d) bring about a reasonable and practicable improvement of the older buildings; (e) secure reasonable, scientific, and economic building laws.

7. To aid in defending such laws when once enacted from the attacks of adverse interests, and in correcting them from time to time to suit changing conditions and meet new needs as they develop.

8. To train and equip workers for the various places of housing reform work.

A part of the anti-tuberculosis warfare, which as a whole is as yet sadly neglected, but which in numerous instances could be carried out at once, is teaching the tuberculous or the predisposed families the invaluable practice of outdoor sleeping. The little device known as the window-tent, which it was my privilege to bring before the profession some years ago, and the numerous similar arrangements suggested and manufactured since then, are suitable and applicable to nearly every home; for even the poorest they should be made common, particularly for people who are obliged to work indoors during the day. More elaborate devices, such as sleeping porches, sleeping balconies, wall-tents, starnooks, etc., are more adaptable to individual homes.

The National Association for the Study and Prevention of Tuberculosis, realizing the inestimable value of outdoor sleeping at night, recently instructed its assistant secretary, Thomas S. Carrington, M.D., to gather material and study the various methods of outdoor sleeping for the purpose of writing a popular book on the subject. The book is entitled "Fresh Air and How to Use It." It is to my mind one of the most valuable contributions to this phase of our tuberculosis warfare. This volume of 250 pages, with 150 excellent illustrations, is sent to all the members of the association, and non-members can procure it at the low price of $1, including postage, by writing to the association, 105 East 22nd Street, New York, or through any bookseller. A smaller pamphlet on the same subject, similar to the one mentioned under the Metropolitan Life Insurance Company's literature, can be obtained free of charge by writing to the association's executive secretary, Dr. Livingston Farrand, 105 East 22nd Street.

To plead for more institutions for the treatment and care of early cases is, as I have already stated, not new in the anti-tuberculosis campaign. But we have of late years become even more cognizant of the fact that institutions for the treatment and care, or we might say with equal emphasis, the isolation of advanced cases, particularly of the vast number which live under the most deplorable hygienic condition constituting an almost certain menace to their kin and neighbor, is of paramount importance if we desire to effectually combat tuberculosis.

The following table, recently published by Dr. Biggs, shows that the mortality from tuberculosis in 1911 was as follows:

| City | 1901 General Death Rate. | 1901 Tuberc. Death Rate. | 1911 General Death Rate. | 1911 Tuberc. Death Rate. |
|---|---|---|---|---|
| Paris | 18.2 | 4.32 | 16.7 | 3.59 |
| New York | 19.91 | 2.29 | 15.13 | 1.76 |
| Boston | 19.87 | 2.36 | 17.08 | 1.55 |
| Philadelphia | 18.26 | 2.23 | 16.50 | 1.87 |
| Chicago | 13.93 | 1.42 | 14.55 | 1.66 |
| London | 17.24 | 1.81 | 12.71 | 1.14 |
| Berlin | 18.00 | 2.18 | 14.65 | 1.78 |

The mortality from tuberculosis in the United States has been estimated by various experts to be about 200,000 per annum. From observations in cities where the most careful tuberculosis statistics are kept, as for example in Cleveland, Ohio, it has been positively shown that to every death from tuberculosis there are eight living tuberculous invalids capable of propagating the disease unless they are conscientious and trained in prophylactic measures or segregated in institutions. In our estimates for the care of tuberculous patients who are in need of institutional care we have made heretofore the number of deaths the basis for our calculations. One of the newer conceptions in the anti-tuberculosis problem must be to multiply by eight the number representing the deaths in order to know what we really need in the line of providing proper home or sanatorium care for our fellow citizens afflicted with tuberculosis.

In the United States we have at this time 525 hospitals and sanatoria for the tuberculous, representing accommodations for about 30,000 patients. Although hopeful and inspiring when compared with conditions of 20 or even 10 years ago, this number still offers only a drop of relief in an ocean of woe.

Poverty seems responsible to a very considerable degree for the prevalence of tuberculosis. The New York Association for Improving the Condition of the Poor has just announced the result of the investigation of 6,565 families that sought aid of the association between October 1, 1911, and June 30, 1912. Of this number, 1,605 sought aid because of illness, and the illness in 555 families was tuberculosis. This would indicate that 8 per cent. of the destitution in the homes of the city during

the above-named period was due to tuberculosis. The association says that some effective plan of home treatment must be found, because it will be many years before there will be enough hospitals to accommodate all the tuberculous patients. A comparison of the hospital provisions in the United States with the needs and growth of population shows that the demand is increasing twice as fast as the supply.*

London offers the lowest death rate of the world's great cities. The isolation of advanced cases to which our English coworkers attach the greatest importance, is said to be responsible for this remarkably low death rate from tuberculosis.

You are perhaps familiar with the very effective work which Mr. Homer Folks, this year's president of the National Association for the Study and Prevention of Tuberculosis, has done in the capacity of Secretary of the State Charities Aid Association. The Committee on Tuberculosis of this Association has worked and is working for the establishment of a tuberculosis hospital for advanced cases in every county of the State of New York. Mr. Folks expresses the hope that by 1915 there will be no uncared-for tuberculous individual in the State of New York.

I do not know if Mr. Folks includes the City of New York in his prophetic hope, his activities having not taken in the metropolis. Be this as it may, years of experience as senior attending physician to one of our largest tuberculosis hospitals in New York City, where the vast majority of patients are advanced cases, has taught me another new phase of the tuberculosis problem connected with the care of the tuberculous poor in the latter stages of the disease where isolation would seem imperative.

We now have in a few States of the Union, as we have in New York City, a law whereby the consumptive, considered a menace to his fellowmen, can be forcibly removed to one of the tuberculosis hospitals. The respective paragraph authorizing the removal of such patients is found in the Sanitary Code, Section 139, and reads as follows: "Whenever an inspector of this department shall report in writing that any person sick of any infectious disease, under such circumstances that continuance of such person in the place where he or she may be, is dangerous to the lives of other persons residing in the neighborhood, the sanitary superintendent * * * upon the report of the medical inspector of the department, may cause the removal of such person to one of the hospitals under the charge of this department or to a hospital delegated by the Board of Health."

To the best of my knowledge there are at this moment neither in the City of New York nor in any other of our larger cities sufficient accommodations to thus segregate all those who by reason of their environments ought to be placed in hospitals.

Why is it that so many patients must be forced to go to the hospital? Why do they not go voluntarily? Why do so many who go voluntarily become discontented and long to go back home where the hygiene and food may be poor and medical care wanting entirely?

Instead of enumerating all the objections which I have heard from patients or friends of patients, and the reasons why the latter do not wish to go or do not wish to stay in the hospital, let me suggest at once the remedies for this situation and then you will perhaps realize with me that it is indeed a new phase which we campaigners in the antituberculosis warfare must consider very seriously.

The great educational campaign has taught the consumptive and those living with him that a hospital for consumptives means a place to die in; a sanatorium a place to get well. My remedy for this is to call the institution in the city or near the city, destined to take care of advanced cases, "sanatorium-hospital" or "hospital-sanatorium." Because the advanced cases among the poor consumptives in large cities are numerous, the existing institutions are often overcrowded. Old former general hospitals are used for the care of such cases, and because of the seeming hopelessness of many of them relatively little care is bestowed upon all. If we wish to attract the advanced cases to such hospital-sanatoria we must above all make the place attractive, even beautiful. We must bestow upon our consumptive poor, though they are no longer in the incipient or early stages, the same care and comfort which are given to the well-to-do who are received in many private sanatoria in the advanced stages as long as they are able to pay. The disease in some advanced tuberculous cases can be arrested, in many their lives can be prolonged and made comfortable, and in not a few instances even an economic* cure can be accomplished.

That we often encounter objections to entering a sanatorium even among the earlier cases and also the well-to-do, is a well-known fact. This prejudice on the part of patients to entering sanatoria arises mainly in their fear of having to associate with individuals whom they consider more ill than they are themselves. Education through appropriate literature and tactful explanation on the part of the physician who sends the patient to the sanatorium, are the only remedies for this sanatorium-phobia.[6] A more serious reason why the poor consumptive hesitates to enter or to remain any length of time in a sanatorium or hospital, no matter how attractive and well equipped it may be and how kindly he may be treated, is the thought of those left at home who may have been more or less dependent upon him.

I know from my sanatorium and hospital experience how badly the patient will do when anxiety and grief is added to his physical suffering; how his appetite will improve, serious symptoms will subside when the cause for his grief and anxiety has been removed. The care of the family when the tuberculous breadwinner is incapacitated, whether in sanatorium, hospital, or at home, is one of the newer phases in the anti-tuberculosis warfare which must receive our most serious attention. In Australia there exists a special tuberculosis invalid pension and ten shillings per week are granted to those in need and unable to work.

Among the following activities which form the basis of our Health Department's work in New York, there may be relatively little that is new, but the summary of this tuberculosis work as it is now

*The State of New Jersey recently enacted a bill entitled "An Act Concerning Tuberculosis" (Chapter 217, Laws Session of 1912) which in its provision for hospital facilities is the most advanced and efficacious thus far enacted by any State.

*By economic cure is to be understood a condition in which the disease has been sufficiently arrested to allow the trained patient to take up some occupation whereby he can earn his livelihood without aggravating the relatively quiescent stage of his disease and, of course, without endangering those with whom he has to work and associate.

being carried on is a strking example of what can be done by an efficient health department of a great city.

There is (1) the notification and registration of all cases of tuberculosis, which was started in 1894. (2) The free bacteriological examination of sputum to facilitate early and definite diagnosis. (3) Educational measures of various kinds, circulars, lectures, newspaper articles; tuberculosis exhibits in the various parts of the city including outdoor exhibitions with moving pictures during the summer months. (4) Visiting of consumptives in their homes and continuous supervision of cases in tenement houses by a corps of trained nurses. (5) Free disinfection by the Department of Health, and issuance of orders for the renovation of rooms vacated by consumptives. (6) Reference of cases to proper charitable organizations. (7) The provision of five classes of institutions:

*a* Free hospitals for advanced cases;

*b* Free clinics for diagnosis and treatment of ambulant cases unable to go to sanatoria;

*c* Free sanatorium for incipient and early cases;

*d* Free day camps;

*e* Establishment of the Tuberculosis Hospital Admission Bureau, for the proper selection of cases for institutional care.

(8) Forcing certain cases of patient into a hospital and retaining them there. (9) Enforcing regulations concerning spitting in public places. (10) Enforcing regulations forbidding use of public drinking cups. (11) Research studies concerning the mode of infection, the rôle of bovine tuberculosis, characteristic of the tubercle bacillus, etc.

An equally comprehensive program containing some newer phases of the problem and which in its ensemble might be considered a model for health ordinances for cities which are resorts for consumptives to follow, is contained in the report submitted to the Section on Preventive Medicine and Public Health of the A. M. A. at the session held in Los Angeles in 1911.* The subjects dealt with in these health ordinances are as follows:

I. REGISTRATION.

Physicians' Duty to Report all Cases of Tuberculosis.

Duty of Authorities and Hospitals, Sanatoria, etc., to Report all Cases.

Duty of Managers or Owners of Hotels, etc., to Report all Cases.

Duty of Department of Health to Visit Patients in Hotels, etc., not Attended by Physicians, and to Leave Literature.

Duty of Department to Make Microscopic Examinations, and to Leave Literature, at Request of Physicians.

Duty of Department to Keep a Record of all Cases.

Penalty for Wilful Misstatement by Physician.

II. SCHOOL CHILDREN.

No Tuberculous Child, or Child of Tuberculous Parents is to be Admitted to School Except by Permit from Department.

III. DISINFECTION.

Premises Vacated by Tuberculous Persons to be Disinfected.

Such Premises not to be Reoccupied Except as Permitted by the Department.

Placard to be Placed on Door of Infected Premises.

Unlawful to Dispose of Belongings of Diseased Persons Unless Disinfected.

IV. PUBLIC FOUNTAINS AND DRINKING CUPS.

No Fountain is to be Erected in Public Places or Buildings Unless Properly Constructed; No Drinking-Cups to be Attached to Public Fountains Unless Provison be Made for Properly Rinsing.

V. EXPECTORATION.

Illegality of Expectorating in Public Places.

Posting of Notices Regarding Danger and Illegality of Expectorating.

Duty of Police and Others to Cause Arrest of Offenders.

Placing of Cuspidors for Use of Public and Employees.

VI. LAUNDRY.

No Linen of Tuberculous Persons is to be Handled at Public Laundry Unless Sterilized.

VII. STREET SWEEPING.

Frequency of Sweeping and Removal of Dirt Once Every 24 Hours.

Time and Method of Sweeping and Removal of Dirt between 6 A.M. and 11 P.M. and Previous Flushing and Sprinkling with Water.

VIII. FOOD AND DRINK.

Premises where Food is Sold Not to be Occupied as Living Rooms.

Articles of Food Carted Through Streets to be Properly Protected from Dirt, Dust, and Flies.

Articles of Food Offered for Sale to be Properly Protected from Dirt, Dust, and Flies.

No Tuberculous Person to be Employed at Manufacturing or Selling Foodstuffs.

Penalties.

IX. GARBAGE.

Duties of Owners, Tenants, etc., to Provide Proper Receptacles for Garbage.

Manner of Collection and Removal of Garbage, Once in 24 Hours, in Watertight Tank and Closely Fitting Cover.

Garbage Not to be Used for Filling-in Purposes, or as Food for Animals Unless First Cooked.

X. MANURE.

Accumulation of Manure in Vicinity of Dwellings Illegal Except as Approved by Department of Health.

Manner of Removal and Disposal of Manure, etc. Removed at Intervals Prescribed by Board of Health.

XI. SMOKE.

No Dense Smoke to be Emitted Into Open Air from Any Building or Engine.

There is one feature of the dissemination of tuberculosis which, to my mind, has been overlooked by most of our authorities. I refer to the tuberculosis germ carrier who is not under the care of a physician. Such individuals are far more numerous than we think. Among these are, first of all, the patients who, although known to be tuberculous, think themselves free from tuberculosis germs because one or two examinations of the sputum were negative. Unfortunately, there are still some physicians who likewise consider the presence of the bacillus in one or two specimens of sputum as the only positive evidence of tuberculosis.

Besides the typical tuberculous patient without medical supervision or who has passed through the hands of a careless practitioner, there are the vast number of patients who go through life with rela-

*Report by Committee: G. Walter Holden, M.D., Denver, Col., Chairman; W. Jarvis Barlow, M.D., Los Angeles, Cal., and H. Anderson, M.D., El Paso Tex., *Jour. A. M. A.*, Dec. 9, 1911, Vol. LVII, pp. 1897-1900.

tively little functional disturbances, nay, even attaining old age because an early attack of tuberculosis has conferred upon them a relative immunity. Then there is another group of tubercle bacilli carriers who, on examination, show almost a normal chest and still their sputum is positive. I do not even venture an explanation for such a condition, but all those who see and examine a good many patients will and must admit that these seemingly physiological bacilli carriers exist.

The greatest danger arises, of course, from the bacilli carriers without a home. Our tuberculosis committee recently made an investigation which revealed that among the 29,460 cases of tuberculosis registered at the Department of Health of New York, 5,053 were homeless. Of these 1,064 were actually without any homes, 2,099 were reported as "not found," 1,346 lived in lodging houses, and 544 in furnished rooms.

Aside of these homeless individuals there is that, alas, vast number of tuberculous patients among all classes of society who, although they know that they are bacilli carriers, still are careless in the disposal of their sputum or become so from the lack of provision of sputum receptacles.

The remedies I venture to offer to do away with the source of infection arising from these knowing and unknowing bacilli carriers are as follows: examination and reexamination for tuberculosis, including repeated sputum examinations, of every individual who desires to seek employment in no matter what sphere. By such a policy the number of careless, homeless bacilli carriers may certainly be diminished. A careful physical examination should also be made of all school children and students in high schools and colleges, parochial and private schools, also of the inmates of prisons and reformatories, and of all municipal and federal employees and officers.

Because of the very nature of the work of our post-office employees,[7] their handling of mail bags, packages, letters, and stamps which in turn are handled by the public, the stamps being moistened with saliva by the aid of the tongue, these employees should be examined and periodically reexamined and no bacilli carrier permitted to continue to do work whereby he may become a source of infection. When one watches the selling of stamps at the average post office in city or country and sees how the gummed side of the stamp passes over the window ledge which is fingered by hundreds of individuals every day, one cannot help feeling convinced of the likelihood of the transmission of tuberculosis and other microbic diseases by stamps and even letters. It should be taught to old and young that licking stamps is dangerous because of the possibility of contamination.

The masses should be educated to the effect that the sputum of any individual may be infectious, that it is dangerous to expectorate anywhere except in the middle of the street where the sputum may have a chance to be rendered inoffensive by the sun and air and will have little chance to be carried on the soles of people's feet into the houses. In public buildings and wherever possible, sputum receptacles should be installed with covers to prevent flies and other insects from getting at the sputum. They should be well kept and frequently cleaned, and above them should be placards explaining the danger from promiscuous spitting. But instead of the headline "Do not spit here" or "Do not expectorate" we should rather attract the attention of the individual who must spit by the positive command, "Spit here."

Everybody should be taught that to cough without holding one's hand before his mouth is not only impolite but dangerous. All kinds of germs such as those of tuberculosis, grippe, and pneumonia, may be expelled with the small drops of saliva ejected during the so-called dry cough. The danger from droplet infection should be mentioned in the circulars prohibiting indiscriminate expectorating.

The masses should be most thoroughly educated concerning the danger arising from the careless spitter. This is, to my mind, one of the most important ways of diminishing the sources of infection arising from the bacilli carriers. For the comfort of the individual who may be so unfortunate as to be a tuberculosis bacilli carrier, let it be known, however, that by the proper personal care he may become a perfectly safe individual to associate with. His case is not at all to be compared with the typhoid fever carrier who should be isolated until all evidence of his being the disseminator of disease germs no longer exists.

The Chautauqua Salute, the waving of handkerchiefs by the entire congregation in honor of some person present or to express their religious joy, is, to my mind, a dangerous practice, as these handkerchiefs may often contain dried infectious pulmonary and nasal secretions. This custom should be suppressed by enlightened clergymen. It is particularly dangerous within doors.

The next important problem and a relatively new one is the employment of a discharged tuberculous patient. Until recently it was held that the best occupation for the cured tuberculous individual was farming, horticulture, or a similar outdoor occupation. When the individual who has contracted tuberculosis had been a farmer, the return to outdoor work when cured might be the ideal, but to make a tailor, a shoemaker, a carpenter, a bookkeeper, clerk, or teacher into a farmer after he has spent six months to one year at a sanatorium in an enforced physical idleness is an entirely different problem. Those who have studied the question most thoroughly are now convinced that it is best to return the cured patient not to his former environment, but to let him go back to his former occupation under improved conditions with his new knowledge of hygiene, his new need of fresh air, and the experience he has gained as to the amount of work he can do.

Many of our more progressive sanatoria resort to occupation therapy as a means of strengthening and improving the patient's health. Graduated labor is, to my mind, one of the most valuable modern adjuvants we have in the hygienic and dietetic treatment of the tuberculous patient. The problem of occupying the patient arrested or cured, discharged from the sanatorium is a difficult one. He is rarely strong enough at once to return to his former occupation and resist the debilitating influence of overcrowding by day and night. I would suggest therefore in connection with our system of sanatoria and sanatoria-hospitals, intermediate stations which you might call health work stations where patients may be able to resume their former occupation in exceptionally good sanitary environments for at least six months after their discharge from the sanatorium. I am convinced that such intermediate stations would greatly reduce the number of relapses and much of the vast sums we are now spending for the care of tuber-

culous individuals would not have been spent in vain.

In a recent paper read before the State Medical Association of New York, I showed that we spent last year in our city over $2,000,000 for the care of the tuberculous and yet of the estimated 50,000 tuberculous patients of New York City, 10,258 died. This is far too large a percentage for the sacrifices made by the taxpayers and the medical profession. I hold the frequent relapses and the hasty return of the half cured patient to his former occupation in the same environments responsible for this altogether too great morbidity and mortality. Dr. David R. Lyman of the Gaylord Farm Sanatorium, at Wallingford, Conn., has demonstrated that the arrested cases when following their usual trade under better hygienic conditions, live better and consequently longer because of their earning capacity being better than if they had endeavored to learn a new trade.

Prof. Fisher showed that in this Gaylord Farm Sanatorium, with which he is also connected, it actually "pays" the State of Connecticut in cold cash to save the lives of consumptives, especially incipient consumptives. The $200,000 expended in this work has resulted in restoring so much working power that already those discharged from the institution have earned $300,000 and still have a potential earning power, good for many times this amount. On the basis of this experience, he concludes that every dollar expended in such institutions saves in a short time at least five dollars, to say nothing of the gains to the consumptive himself. At present, about fifteen million dollars a year is put into the tuberculosis fight in the United States. When several times this amount will be invested—enough to isolate or at any rate "educate" every one of the million-odd consumptives in the United States, now spreading infection—we may expect to see the beginning of the end of the great white plague. We must be more rational in our prophylaxis as well as our treatment and in the aftercare of our consumptives, otherwise we will never master the disease.

As one of the newer problems in our fight against tuberculosis, I would be remiss in my duty would I not mention the all absorbent question of the high cost of living. Not to have enough food or not enough nutritious food predisposes to tuberculosis. Every phthisiotherapeutist knows that ample food and good food is one of the essentials in the successful treatment of tuberculosis; and furthermore, those of us who are interested in the treatment of the tuberculous poor in institutions or at home, know what a problem it is nowadays to make both ends meet, and yet provide enough nutritious food for those under our care.

I am not enough versed in statesmanship or politics to suggest a remedy along that line. The only thing which appeals to me likely to serve as an amelioration or perhaps even a rational remedy for the situation is to follow the advice of men like Mr. James J. Hill,* Professor Cook of Yale,[8] and the numerous experts of our Agricultural Experiment Station. Philanthropists and generous minded citizens in general should cooperate with these experts to make agricultural life profitable and also pleasant. When by the provision of sound and sane social enjoyment and intellectual advancement for the young generation of farmers living in the country can be made as attractive to young people as living in the city, when the farmers will have been taught to double and treble the yield of their products, and when transportation to the consumers will be made easy, farming will become an occupation to be sought by many. Its returns will be profitable and the consumer will receive the products which he needs at a cost within his means.

I come lastly to that phase of the tuberculosis problem for which it is difficult to find a name but which we might call "shifting the responsibility,"—sending patients away to be cared for by others. Whether this shifting of responsibility is done conscientiously or not, it is not fair. The Governor who pardons a tuberculous prisoner without being sure that this tuberculous individual will not become a burden to his family or the community, is not doing a fair thing. The Eastern municipality, physician, or any individual who sends the poor consumptive to a Western State to let him there fight for himself until he becomes a burden to the strange community, is not doing a fair thing.

How keenly this injustice is felt you will see from the fact that near the middle of April of this year, at the call of Governor O. B. Colquit of Texas a Southwestern Conference on Tuberculosis convened in Waco, Texas, to consider "ways and means of aiding the tuberculous stranger in the Southwest and to discourage further migration of indigent consumptives to Southwestern States."

The steamship companies who send their agents throughout Europe, advertising cheap rates, holding out great promises to the emigrants and bringing them here with tuberculosis to become a burden to the community, do not do a fair thing.

What is the remedy? Let us enlighten our pardoning governors on this subject. Let them be impressed with the fact that any discharged tuberculous prisoner with an open tuberculosis constitutes a menace to the community. The discharged or pardoned tuberculous prisoner is often, because of his social status, even a greater menace than the ordinary tuberculous individual. If special sanatoria for this class of patients are needed let them be established by the State.

Against the injustice of unloading the consumptive poor of one State into another, the above mentioned conference in Waco suggested a very good remedy which was advocating the publicity as to lack of free hospitals for stranger consumptives in those sections, the inability of charity organization societies to aid such, the difficulty of securing suitable employment, and the fact that consumptives coming to the Southwest should have funds sufficient to carry them for about one year. Of course, making the problem of the consumptive poor as much a state and federal problem as it is now a city and state problem, would be the most rational solution. Let a federal department of health assume the responsibility of controlling the care of all the needy consumptives and let state and city anti-tuberculosis agencies act under its supervision, and such injustice as making one state pay for the consumptive poor of others would not be possible. A good suggestion was made at the above mentioned conference, namely, to call upon the federal government to convert abandoned forts and military reservations in the Southwest into sanatoria-hospitals for consumptives. In the meantime let every citizen realize the enormity of the offense of sending a consumptive without means to another State, and let him be punished for it if discovered.

*Letter to the *New York Times* of August 24, 1912.

Again, what can we do to stem the tide of tuberculous immigration? This is also a large subject and worthy of separate consideration.* Tuberculosis must be considered a world problem, a problem for every civilized nation. Let European governments understand that they must take care of their own tuberculous people as we take care of ours, and that in the end, by united efforts, it may be possible to conquer the white plague in all countries.

Every prospective emigrant should be examined to ascertain his freedom from tuberculosis by two competent medical men, one appointed by his home government and one by the steamship company which is to transport him to this country. A certificate showing freedom from tuberculosis, signed by these two medical men should be in the possession of every emigrant wishing to come to these shores. An individual discovered to be afflicted with disease should be returned to the care of the authorities of the city or village from which he came with the diagnosis and recommendation for treatment. Exceptions can and should be made in the case of an individual with ample means who is simply visiting, or seeking to recuperate his health by a change of climate, or desirous of entering an American sanatorium for treatment.

The laws relating to deportation should be changed to the effect that if the holder of any such certificate, or any immigrant develops tuberculosis within six months to one year from the date of his arrival here and becomes a charge to the community, he shall be deported to the port whence he came. The expenses for this deportation should be borne by the steamship company who brought the immigrant to our shores, and not by the State Board of Charities.

The suggestion has been made that physicians of the Public Health and Marine Hospital Service be stationed at the important points of departure in Europe so that each emigrant can be thoroughly examined, and those entitled to a clean bill of health be allowed to take passage. I question whether the international law would sanction such a procedure. Secondly, there are too many minor ports from which emigrants could take passage and escape the United States Government physicians' examination. Of greater value would it be for foreign governments and steamship companies to make it known that if a man expects to stay in the United States he must not become a public charge; that he must be physically, morally, and mentally sound. With such publicity and the additional examination in the manner above outlined, the United States Government will be less burdened with the care of tuberculous aliens who, uncared for, are a constant menace to the community.

For want of space I must refer my readers for further details to the article on this subject in the MEDICAL RECORD of July 13, 1912. I might, however, add here a very valuable suggestion made at the recent International Tuberculosis Congress in Rome by Dr. Antonio Stella of New York. It was to the effect that every emigrant should be insured against tuberculosis, the cost of insurance to be added to the price of the steamship ticket, the policy entitling the bearer to return transportation and free treatment in a sanatorium, in the event of his contracting tuberculosis within a specified time.

I hope that through federal control we may obtain fair play regarding tuberculosis emigration from one state into another, and through international agreement, from one country into another, and may thus justly distribute the burden we have to bear and I am sure are willing to bear. The eradication of tuberculosis from our midst is not an easy thing. The greatest of all predisposing causes—poverty, want, bad housing, insufficient food, lack of employment are not new phases of the tuberculosis problem. They confront us at every step, more urgently to-day than yesterday. They are known to you as they are known to me and they will need attention, for not until there will be more social justice, a more wise understanding and generous fulfilment of our obligations toward our less fortunate brothers and sisters, may we hope for victory over the great white plague. Fortunately the skies are clearer. Instead of asking "Am I my brother's keeper?" many truly great and noble minded men and women say "We must be our brother's keeper." According to the fourth annual statement issued by our National Association, nearly $19,000,000 were spent in the anti-tuberculosis campaign in the United States during the last year. Thus, it is true, much has been done of late, but there is much more for all of us to do. May our labors be blessed and crowned with success.

*I made it the theme of a special paper, entitled "The Immigration of the Tuberculous into the United States. A Problem for Every Nation." It was intended to be read before the Congress on Tuberculosis in Rome last April, but owing to my inability to be there it could only be read by title, but it was read in full at the recent Symposium on Immigration of the meeting of the American Academy of Medicine in Atlantic City, and appeared in the MEDICAL RECORD of July 13, 1912.

## REMARKS UPON THE GASTRIC MOTOR FUNCTIONS.

BY CHARLES SUMNER FISCHER, PH.D., M.D.,

NEW YORK.

IT is only within comparatively recent years that the motor functions of the stomach have received the clinical attention which they deserve. This refers especially to the minor disturbances of activity. Unless these functions were affected to almost a surgical degree, calling for mechanical interference, they were considered in a superficial manner. Certainly, it has not been the custom to attribute to the lesser motor affections their due importance and influence in shaping the development of the ordinary gastric diseases. Not only does the progress of any gastric disease, however, depend upon the behavior of the motility of the

organ, but most of the distress of the chronic dyspeptic is due to it. It is fairly well established that the average stomach can support a very decided acidity without rebellion, and it is only when in the course of the disease a disturbance of relationship between acidity and motility occurs, that the ordinary symptomatology of dyspepsia begins. Most of the distress of chronic gastric conditions is due to changes of intragastric pressure and not to chemical changes in the food contents. Intragastric pressure depends primarily upon muscular tone, and it is the influences bearing upon the latter which are of primary importance in determining the final result in each case. In this respect remote influences are very apt to be underestimated. This attitude is manifestly unreasonable, for it is fair to assume that whatever bearing such influences may have upon the secretory functions, they must necessarily exercise the same upon the motor functions.

As most cases of chonic dyspepsia are resolved by analysis to a basis of disturbed relationship between acidity and motility, the question always arises as to which function succumbed first. So heated was the discussion upon this topic at one time that the camp of gastrologists was fairly divided into obstructionists and non-obstructionists. Given advanced cases of hypersecretion with food retention the primary disturbing cause was attributed to either one function or the other, according to the particular bent of the individual. The decision depended upon physiological or mechanical mental tendency. Surgery has always favored the obstructionist view, and indiscriminate gastroenterostomy became the rage. Fortunately, a healthy reaction has set in, due partly to many recurrences of symptoms following operation, due also to a better knowledge of the regulating mechanism of the motor functions themselves.

This question of priority must always possess a certain purely scientific interest apart from its practical bearing. It can be partly decided from its biological aspect. Regarded in the latter light, all digestion can be looked upon as a self-preservative and defensive measure, and as all defenses of organic life were at one time chemical, the actual digestive secretion should be regarded as first in importance, to which all other activities are subservient. As digestion expanded, however, and the chemical processes concerned became more complicated, muscular changes in the alimentary tract kept pace accordingly, so that from the simple passive pouch of primitive life there gradually developed the extensive digestive system of the present-age vertebrate. Always, however, has this muscular development been subservient to the chemical function, and in this light it should be judged.

In a broad survey of the whole field of digestion these well-known facts are not as irrelevant as would appear at first sight. Into every case of advanced disturbance of relationship between acidity and motility, this question always projects itself —often with great practical significance, and while it cannot always be decided positively in the individual, on account of complicating factors, it can be said in a general way, by reason of this biological development, and substantiated by the histories of the great mass of clinical material, that the secretory function was the first to succumb, to be followed by changes in motility as a matter of accommodation, adjustment, or protection. The muscular structures act as protectors against excessive secretion or as aids to diminished secretion. Hence, it is that in cases of excessive gastric secretion the tendency is always toward retention, whereas in diminished secretion the opposite effect or rapid expulsion results. In the intestine the relationship is the reverse. Excessive secretion is followed by rapid expulsion and *vice versa*. These fundamental physiological facts should always be borne in mind when judgment upon obscure conditions of secretion and motility of the whole alimentary tract is demanded.

With such a parallelism of evolutionary development, it is evident that the regulating mechanisms of the two systems must be more or less alike, so that any influence affecting the one must necessarily affect the other. It is impossible to conceive any distinction in this regard. Both systems must respond in their respective fields of activity, in like manner to like influences. It is not probable that conditions that stimulate the secretory function would depress the motor function. Hence, all those remote influences which have heretofore been judged competent to affect the secretions, not only the immediate physiochemical or psychoneurotic influences of adult life, but also the distant pernicious dietetic habits of childhood and hereditary predisposition, must have a direct bearing upon the motor functions. It is these remote influences, included among the latter, which have not received the consideration they deserve, for it is they which determine in great measure the probable course of development of motor dyscrasias of later life.

That tendencies affecting the motility of the gastrointestinal tract can be transmitted is sufficiently evidenced by the familiar types, gastric atony, chronic constipation, or chronic diarrheas. These are but hereditary tendencies to hypo- or hypermotility. They do not indicate that a child inherits an abnormal musculature. They more likely indicate a definite mode of response on the part of the musculature to external or internal stimulation. They are conditions of disturbed equilibrium between excitation and inhibition, and as such are distinctly hereditary. These tendencies are present and potent in every case and guide the destinies of the cases, so that, given a certain number of individuals, subject them to the same insults, and we will see in a certain number sluggish activity, and in others hyperactivity in the propulsion of the chyme content. The early recognition of these tendencies is of considerable practical importance. This should be done, if possible, in each case before any local readjustment—sure to occur as the case advances—has had time to obscure this fundamental issue involved. Thus, in many cases of the familiar combination of hypersecretion and retention, an early examination would have revealed both hypermotility and hyperchlorhydria. Had this principle been inculcated into gastrology earlier, much discussion about primary pyloric obstruction would have been avoided.

These, however, are the extreme cases. We are dealing here more with the average cases as they occur in practice or clinic, states in which the graver conditions of myasthenia have not developed. While it is generally admitted that the minor emotional states have a direct influence upon the secretions in these cases, no special attention has been directed to their influence upon the motor function. These were supposed to proceed normally, except perhaps in cases of severe shock. When

we consider, however, that 90 per cent. of our ordinary chronic dyspepsias possess a determining neurotic element, that 90 per cent. of these neurotic elements are of the type known as anxiety neuroses, in which the emotional state is liable to be markedly exaggerated, and, lastly, that 90 per cent. of the disagreeable sensations in the stomach experienced by these individuals are due to either increased or decreased muscular tone of the stomach, it becomes evident that the minor influences of everyday life must bear directly upon the muscular activities themselves, and that the determination of these activities, their present and past tendencies, is an item of considerable moment for a proper estimation of every case.

As the object of a series of tests of the gastric secretions under varying food intake is to determine the average secretory capability of the organ, so here the object must be to determine the general motor capability. In order to accomplish this effectively repeated observations are necessary. Just as the secretions may vary quantitatively from day to day under various influences, so the motility may vary. This is especially true in the neuroses, where days of depression may well be accompanied by loss of muscle tone, only to be followed on succeeding days by exaggerated contractibility as a result of general irritability and hypertension. Single examinations under these circumstances may well lead to false notions of motility, and would only determine the state existant at the time and for the particular circumstances operating at the time. Hence, both atony and hypermotility may be diagnosed on succeeding days, in the same individual, which, in case only one test is made, would obviously lead to incorrect conclusions.

In endeavoring to determine the various effects of changing daily conditions upon the gastric motor activities, we encounter the same difficulties attending such determination in the secretory sphere. Why an emotional state should induce hyperchlorhydria in one individual and hypochlorhydria in another, is beyond our present knowledge. Corresponding enigmas of neurotic projection would be the very prevalent anorexia and the occasional bulimia, the frequent nervous diarrhea and the rare spastic constipation. Whatever explanations may be offered for these directly opposed conditions there can be no doubt that they follow some law of determinism. It is certainly reasonable to suppose, in this connection, that the inborn tendencies of muscular innervation must wield a very considerable influence in determining the immediate effects of the daily insults of modern life, both upon the secretion and motility of the stomach, and that the final outcome of chronic conditions will depend largely upon such tendencies.

To a certain extent the effects of insults to the stomach, from without or within the organism, can be explained by biological conceptions. They are defensive measures primarily intended to guard the general organism. The great frequency of certain forms must have been apparent to all observers. In the secretory province it is excessive secretion. It is pretty safe to assume that the great majority of secretory disturbances start as excesses, which in the course of time are modified by local conditions. Every danger to the organism arouses activity of function, not passivity, and excess of hypochloric acid in an insulted stomach is but a natural result of such danger. Normal stomachs must respond in this manner. In lowest organic life digestion is the only method of defense. Hence, this activity has been handed down through the ages. Certain neuroses are classified as "defense neuroses." The same may be applied to gastric conditions. They are defensive measures in the beginning.

The effect of daily influences may not be so apparent in the motor sphere, but they are present always. An emotional state will produce either hypoactivity or hyperactivity. Given the some conditions of habit, life, and environment, some individuals will respond to insult with atony, others with hypermotility. The only reason for this may lie in constitutional tendencies of muscular innervation. It is significant to note, however, that in their early stages most cases exhibit hypermotility. The combination of hyperacidity and hypermotility is the commonest combination of our clinics, and can be elicited in most cases, provided they are seen early enough. This is to be expected, for the biological reasons already stated. The two conditions run parallel for just so long as the hyperacidity does not constitute an active menace to digestion. From the moment this occurs, retardation of the chyme current begins.

That constitutional tendencies are influential in determining local abdominal development has long been known. In so far as it concerns hypotonic states, it has been fully described by Stiller as constitutional asthenia. To it is due much of the atony and most of the ptoses of the organs of digestion. In such individuals the stimuli carried to the alimentary musculature meet with indifferent response. These cases are theortically atonic long before evidence of the same manifests itself.

It is only within comparatively recent years that we have been brought to a realization of the importance of excessive muscular activity, of hypertonicity as such. As gastric hypermotility it has been recognized and described, and its clinical value has been largely connected with the causative relations of such secretory disturbances as hypersecretion. As a clinical entity, however, and as constitutional tendency it has not received much attention. This is partly due to the fact that as a local manifestation it is often only apparent during the early stage of a gastric affection, and can easily be overlooked. It is marked during the later stages by local adjustment and demands.

Hypertonicity, as a constitutional tendency, is quite as entitled to recognition as a predisposing factor in directing the development of local conditions as hypotonicity. In this respect it shows itself very early in life. It is the underlying cause of the various pyloric spastic states of infancy, which are but part of a general lack of inhibitory control. This tendency can well be carried into adult life, in which case the individual exhibits extreme irritability in all the motor areas. In the stomach this would show itself as hypermotility, and is usually associated with its counterpart in the secretory sphere, namely, hypersecretion. Both are due to the same constitutional influences. In such individuals any insult to the stomach will result in this combination for a certain length of time, at least, and it is fair to assume that most of the ordinary cases of chronic dyspepsia started in this manner. The duration of the combination is a matter of individual disposition.

An appreciation of this combination is of some practical value. When we consider that the ma-

jority of our chronic gastric diseases are the result of conditions of life rather than indiscretions, that they are localized in a peculiarly sensitive and naturally predisposed area, that they are determined many times by psychological as well as physiological conditions, and that the final result in each case is entirely a matter of individual disposition, it must be evident that a general conception of the average course of these cases must be of some import. It is often impossible for the general practitioner to make the necessary functional tests. Time for these may be lacking, disinclination may be present. Heretofore, under such circumstances, the usual attempt to guess has resulted in the diagnosis of atony. It has become an automatic conception. How far this can be erroneous may be judged from what has already been said, namely, that 75 per cent. of all secretory gastric disturbances are hyperacid; of these fully 90 per cent. have a decided neurotic basis; of these neurotic states the majority belong to the category of anxiety neuroses; that the effect of anxiety and fear is to induce hyperactivity in all bodily functions. If these conceptions are the correct ones, it is evident that they must have a very practical significance for those who have not the time or opportunity to subject their cases to the customary examinations.

It is to be presumed that the predisposing influences which produce these effects upon gastric function would produce similar effects upon the rest of the alimentary tract. If hyperchlorhydria, hypersecretion, and hypermotility may be expected in the stomach, the intestines should respond with diarrhea and hypersecretion. In a small proportion of cases this does occur for a certain period of time. In the majority of cases, however, the very conditions in the stomach militate against like conditions in the intestine. This may be accomplished by a decided pyloric reflex. The excessive secretion in the stomach may induce a compensating dryness of the intestinal contents. Again, the intestine presents a remoter automatism, does not stand in the same close psychic relation to the individual; hence, the forces of habit, environment, and emotion are not so effective and affective, are distributed over a much more extended area, and lose their power proportionately. Further, if the evil effects are present in the small intestine, they may be marked by the automatic arrangements and reservoir capacity of the large bowel. In this manner an alimentary tract which gives all evidence of hypermotility and hypersecretion at its beginning may exhibit hypomotility or constipation at its end. These diverse effects of external influences upon the two ends of the alimentary canal are facts of common observation. The motor function of the stomach is quite beyond help from the usual voluntary general motor activity. Bodily exercise plays very little part here. In the intestines active voluntary exercise aids the local activity. Hence, individuals who lead sedentary lives and suffer from chronic constipation in consequence, may exhibit contemporary gastric hypersecretion and hypermotility.

The importance of a comprehensive understanding of the subtler features of motor disturbances is evident. The course, duration, and final result, in each case, will be determined by these. Heretofore, the final results have largely engaged attention—atony, dilatation, displacement, obstruction. Clinically, comparatively little regard has been directed to ultimate reasons or predisposing tendencies. Psychic tone must now be recognized to the same extent as psychic secretion. It is half the battle. Most of the symptomatology of ordinary dyspepsia is due to it. Given perfect muscular action and the majority of the secretory anomalies would pass unrecognized. The stomach is extremely tolerant of chemical irritation. It rebels at once against changed conditions of internal pressure as a result of increased or diminished muscular tone. Thus, we may have sensations of fullness or emptiness, apparent gas formation, gnawing, rapid satiation or loss of appetite, painful sensations of any degree, depending upon extreme relaxation or extreme contraction. The inspiration for appetite would seem to depend upon the state of muscular contraction. In short, most of the disagreeable sensations, the little daily discomforts of the chronic dyspeptic, may be traced to either of these states.

These observations must have a practical bearing upon treatment, especially dietetic treatment. Most of us have had our illusions as to the possibility of influencing abnormal secretory conditions of the stomach, by carefully arranged and specific diets, dispelled. All such activity has resulted in failure. Extremes of secretion in the majority of cases have come to stay, and the best that we can do is to so arrange the diet as to meet the disturbed relationship between acidity and motility. Viewed in this light the physical properties of food, its distribution as to time of administration and quantity, acquire greater importance than its chemical composition. The chemistry of food has produced fads and fancies in dietetic management which may impress the patient, but which certainly cannot impress those with any knowledge of the mechanism of these cases. The indigestibility of certain foods remains the same whether the stomach be hypoacid or hyperacid. The simplest example would be that of hard or tough meat. This cannot be administered in achylia because there is no acid to attack it. It cannot be given in hypochlorhydria because of its prolonged sojourn in the stomach. This crude example will serve for all the rest. After a fair trial, extending over years, of the various specific diets for specific secretory conditions, I have come to the conclusion that practically the same chemical constitution of food applies to both hypo and hyperacid conditions in the common-sense management of the ordinary chronic dyspeptic, and that chemical affinities of food constituents to enzyme action as demonstrated *in vitro* in the laboratories, theoretically correct, are of very little value in practice. The general requirements of the average case will be met by fresh meats, roasted, broiled, or boiled, without fat or fiber, fish, only fresh, boiled, broiled, or baked, without made sauces, the avoidance of vegetables prone to fermentation, such as boiled or fried potatoes, onions, cabbage, cauliflower or turnips, simple desserts, such as rice or custard puddings, stewed fruits, and cream. Take these simple products, distribute them over the day at intervals and in quantities determined by local conditions of motility and general conditions of occupation, mental and physical strain, contribute so far as it is permissible to the general contentment of the individual, and we have the safest and sanest method of the dietetic management of the average case of chronic dyspepsia without special complications.

In order to do this intelligently it is necessary to have some data by which the motility, general

or local, may be judged and appreciated. Stiller has given us certain landmarks for the recognition of general hypotonic conditions. In the narrow intercostal angle, the floating tenth ribs, the general muscular relaxation and the tendency to ptosis of the various abdominal organs, we have fairly reliable indications of a general lack of muscular tone, which, in the majority of cases, in order to have produced such results, must have existed from early childhood and been inherent in the individual from birth. For the early recognition of hypertonic conditions we have no such reliable signs, but there are certain features of personality in each case, which can guide us in this respect. In those cases where it is possible to make the necessary local tests of motility, the tendencies can be determined for the stomach, at least. In the majority of cases, however, this cannot be done, and, as a matter of fact, is not done. In these cases the indications must come from general observation. This may reveal the history of convulsions, night horrors, tendency to exaggerated food regurgitation in early childhood or of more or less troublesome colic; in other words, an exaggerated irritability of all motor areas. Later in life this shows itself in general muscular tension and a tendency to localized muscular spasms. There is usually present a hyperactivity of the vasomotor apparatus as indicated by the marked dermographia, poor "distal circulation," or momentary vertiginous attacks. Palpitation is usually pronounced and all the reflexes are exaggerated. In the sensory sphere there exists increased affectivity. All organic response to the emotions is excessive. In most of these cases we have to deal with an anxiety neurosis of varying degree of intensity. There is a concealed propelling force somewhere, and this force projected into the motor areas will produce hyperactivity. These are but a few of the signs. Given these, however, and an environment, habits, or occupation to foster them, and it is pretty safe to assume that in the alimentary tract we will have to deal with hypermotility. This tendency may exist where local manifestations of the same are not pronounced. It may be masked by what in case of the gastric secretions, has been termed the weakness of overstimulation (überreizbare Schwäche, Riegel).

General considerations of the kind attempted in this paper are not popular in gastrology. They, as a rule, meet with an indifferent reception. The practical spirit of the times, here as elsewhere, demands specific methods to meet specific conditions. The stomach is looked upon as an animated machine, and the mechanical gastrologist is having his day. Every new device is greeted with enthusiasm and diseases of the stomach have been uprooted from the soil of medicine and transplanted into the field of exact physical science. One very respected authority in a review of the development of this branch, points out the general mechanical tendency, and goes so far as to predict that the day will come when every competent gastrologist will perforce have to be a surgeon. This certainly constitutes a very gloomy outlook for those whom Nature has not endowed with mechanical genius.

This instrumental exploitation was necessary, important, and unavoidable. It has served its purpose, for it has demonstrated the extent of its usefulness. It has shown that most of the attempts to approach the subject upon purely physical lines, with exceedingly few exceptions, have been futile, and the various contrivances devised for this purpose have retained only an historical interest. Most of them were conceived in a superficial spirit of pure utility, without due regard for physiological difficulty, and were doomed to failure at their very inception.

Careful experimental observation in any gastrological clinic will impress those who wish to see with the fact that there is a vast number of cases which cannot be reached by chemical reaction or mechanical device. We make our routine chemical and physical tests in these cases and stand bewildered before the results. They defy the test tube and the stomach tube. They are the *bête noir* of the gastrologists, and are usually sent about their business with a bottle of medicine and very vague directions as to diet. In these cases too assiduous gastrological application may do more harm than good. The local reactions are immaterial, for they are but accidental manifestations exhibited in this region through remote and predisposing tendencies. These are the most difficult cases with which we have to deal, for they shatter our ideals of technique and demand for their proper appreciation the broadest possible conception of the subject of gastrology in its scientific, psychological, and sociological aspects. These are cases not only for the gastrologist, but also for the psychologist and the educator. Treatment consists of a process of readjustment and reeducation. It demands patience, perseverance, and sympathy, qualities which are noticeably absent in those wedded to strict laboratory methods. Among these strict material causal relationship is demanded.

The time has come for a division of labor in gastrology. There is the purely mechanical side for those interested in concise local organic conditions. There is also the broader philosophical side, which, while not neglecting the advantage gained by knowledge of local conditions, uses these latter only to obtain a proper perspective of the whole.

## HYGIENE FOR THE NORMAL CHILD.*

By IRA S. WILE, M.S., M.D.,

NEW YORK.

The basis of a long life is hygienic living. The struggle for longevity is made difficult through the general ignorance of basic hygienic principles. Hygiene is now a word to conjure with though in the practical affairs of the world it is largely neglected.

Educational institutions are beginning to appreciate the value and importance of instruction in hygiene in the public schools. The stress of present methods has been placed upon securing a hygienic environment for abnormal children. Apparently a premium has been placed upon physical or mental abnormality as a prerequisite to securing sanitary environment or hygienic education. It is time that the rational process of education assumed that the education of the normal child after all represents the main educational problem. The hygienic training of the normal child should be the main element in hygienic education in order to accomplish the greatest good for the greatest number.

The purpose of teaching hygiene should be con-

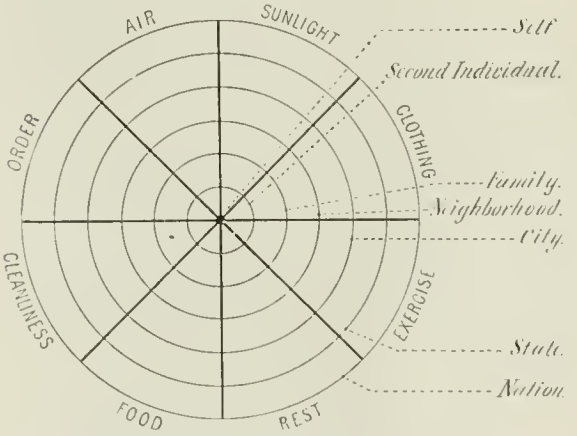
*Read before the Association for the Study of Exceptional Children, November, 1912.

sidered in dealing with methods and in making arrangements for a carefully adjusted curriculum. Instruction in hygiene possesses both a medical and educational value. The medical value is twofold; corrective and preventive. The educational phases of hygienic instruction are cultural, economic, and social.

It appears to be beyond controversion that hygiene for the normal children will affect the bulk of our school population, because 92 per cent. of our school population may be regarded as normal despite the existence of numerous physical defects. Judging from statistical studies, the normal child is not essentially a child without physical defects.

Obviously, in order to secure effective instruction in hygiene, it is essential to secure the instruction over the longest period of time that is practicable. This suggests that hygiene must be taught in the schools throughout during the period of compulsory school attendance.

Taking into consideration the medical inspection of school children of New York City during 1911, it is noteworthy that of 282,463 children examined only 75,369 children were found to be free from the physical defects sought by the medical inspectors. There were 7,913 children with malnutrition, 1,167 with tuberculous lymph nodes, 2,227 with



A diagrammatic scheme for teaching social hygiene.

heart disease, 798 with pulmonary diseases, 3,800 with skin diseases, 1,514 with orthopedic defects, 28,884 with defects of vision, 2,854 with defects of hearing, and 162,962 children with defective teeth. This marked evidence of the nature of the defects that exist in our school population indicates the type of hygienic instruction which is essential for the correction of such physical defects. For example, the dental defects suggest the necessity of teaching the hygiene of the teeth, careful mastication, the use of the tooth brush, the character of the foods which best develop teeth, the care of the primary teeth, the correction of dental deformities, and the relation of the teeth to malnutrition.

The tuberculous lymph nodes call for attention to the hygiene of environment, fresh air, ventilation, the danger of overcrowding, the spread of tuberculosis by direct contact, the germ theory of disease, the value of fresh air, open windows, open-air schools, and similar topics.

The cardiac defects call for the hygienic problems that must deal with circulation, as adequate exercises, proper methods of breathing, the dangers of overstrain, the advantages of physical education, the dangers of overindulgence in athletics.

The pulmonary diseases for corrective purposes require discussion of the hygienic themes dealing with correct methods of breathing, the care of sputum, the danger of infections by direct contact, the value of food, the importance of fresh air, the dangers of dust, the protection of sputa from flies and other insects that might serve to convey the disease to others.

The various skin diseases by inference demand instruction as to the hygienic value of bathing, the various kinds of baths and their general effects, the use and abuse of soaps, the importance and value of individual towels. For the contagious skin diseases the importance of protection of the lesions and the necessity of caring for soiled dressings becomes of paramount value, together with the importance of medical inspection and the advantages of quarantine and isolation.

The defects of vision arouse interest in teaching the proper position when studying, writing, reading, the importance of adequate light, the relation of vision to occupation, the dangers of contagious eye diseases, the relation of optical defects to the general health and the damages that occur to vision as a result of industrial accident and disease. These few random thoughts as to the hygienic precepts which are corrective in nature indicate the importance of hygienic instruction on the basis of the defects that have already been found in our public school children.

The preventive phases of hygiene are manifest in such problems as vaccination before entering school, the exclusion of children by reason of contagious diseases, the system of quarantine and isolation as maintained by the health department, the purpose and value of medical inspection in the school and visiting nurses in homes. The use of individual glasses, cups, pencils, towels, all have their practical prophylactic lessons. Similarly one may develop those sides of hygiene which deal with the care of animals and the possibilities of infection from them. The nature of home hygiene as related to the kitchen, the dining room, the bedroom involving the problems of air, light, food, rest, clothing, and bathing possesses a tremendously potential power for the prevention of physical defects and contagious diseases. It must be understood that the educability and the mental powers of the child are enhanced through such preventive hygienic instruction.

Industrial hygiene as related to the dusty trades, the dangers from metals, dust, and fume, the importance of safeguarding machinery, belts, gears, and saws, the proper adjustment of a man to his labor afford excellent fields of hygiene which may be reaped if the hygiene for the normal child is to be possessed of intrinsic value for his future welfare. It is unfair to permit the child to enter industrial life without a knowledge of the inherent hazards and the best methods of safeguarding his health and welfare during the years devoted to earning his bread and butter.

I might say that the school itself should give rise to some discussion and training. It is difficult, however, to give hygienic precepts in unsanitary school buildings, where most of the principles of hygiene as regards furniture, ventilation, and cleaning are very shamefully disregarded.

The cultural aspects of a course in hygiene may be summarized briefly as securing the relation of hygiene to the various other subjects in the curriculum. It is designed to reveal the interdependence of personal health and the communal health.

The dependence of national health upon laws relating to the sanitary control of cities and states points out a broad principle of citizenship which is altruistic in its conception. Civics and health are closely united. Geography presents many applications of hygienic principles in a consideration of the methods of housing, clothing, and feeding under various climatic conditions in the development of nations. The rise and fall of governments afford many valuable incidents evidencing such hygienic factors as alcoholism, malarial infections, and the contagious diseases. The story of the building of the Panama Canal contains in itself a large series of extraordinary lessons dealing with family, municipal, industrial, and State hygiene. The cultural phases of instruction thus correlated cannot be overestimated.

The economic aspect of such a broad hygienic horizon is reflected in the educational gains that are to be derived from such instruction. As a result of attention to hygiene, fewer absences will result; children will be capable of better education; their memories will be developed, and less retardation will result. It is needless to go into the actual economic gains resultant from an improvement in the mentality of the children and a consequent lessening in retardation.

The essence of educational purpose is preparation for citizenship. Social progress will result from making practical application of hygienic principles to the various affairs of everyday life. A course in hygiene should make children conscious of their civic duties and cultivate a spirit of social hygienic responsibility. One may readily understand the interrelation of environment and personal health. This involves teaching the facts relating to the protection of water supplies, sewage disposal, street planning, and the value and necessity of municipal institutions. Even such problems as parks, playgrounds, street lighting, smoke nuisances come naturally under the head of the subjects that might be given attention in public schools in order to develop intelligent ideas in the minds of future citizens. The social phases of hygiene are especially noteworthy and form an indispensable part of any course of instruction designed for the great body of children who comprise the elementary school population.

Bulletin No. 4, 1911, of the United States Bureau of Education, states: "There is an increasing feeling that this subject should be closely allied to the demands of modern life; particularly is this true in courses of study for city children who live in congested districts." The stress of the teaching should be in the application of hygienic principles rather than an exposition of the underlying theories. Such problems as deal with anatomy may well be relegated to the background. Hygiene should be practical and capable of demonstration and application. The teaching of anatomy possesses little essentially practical information for the child's everyday life. It is unimportant to know how many bones there are in the body or the size and shape of the stomach or the length or the texture of the intestines. It is important, however, to know how to stand and sit correctly; to know the value of mastication and the period of time required for digestion as related to bodily activities; and it is valuable to teach regularity of bowel habits. Wherefore I believe that the teaching of hygiene should precede anatomical studies or the teaching of anatomy should be incidental to those questions of hygiene with which they are correlated.

At the present time elementary school hygiene takes up about 340 minutes per week in our elementary school systems, while music, for example, is given 550 minutes. This serves to indicate how inadequate is our present system of hygienic instruction.

The purpose of education is to protect the State from all dangers arising from ignorance, disease, moral degeneracy, industrial retrogression, criminality, and civic unrighteousness.

Hygiene is the science that treats of the laws of health. Social hygiene is the science that treats of the laws of health, in the broadest sense, as related to the welfare of society as a whole. Social hygiene includes personal hygiene, family, municipal, state, and industrial hygiene.

The expression, "dry as bones," aptly describes much of the recent teaching of physiology and hygiene. In the mode of teaching the cart is placed before the horse. The average child will readily grasp and appreciate the facts that are essential to the correct mode of living while it lacks the interest so necessary to stimulate attention to the wired assortment of anatomical and physiological statements that are supposed to form an essential part of the school curriculum.

Considerable knowledge of the close harmony of the various parts of the body may be acquired in a normal manner through the study of hygiene. The appreciation of the reasons for the hygienic principles that tend to prolong life and to promote bodily health necessitates an understanding of the most practical facts in anatomy and physiology.

A careful analysis of the general subject of hygiene discloses the fact that it is based upon the consideration of a few fundamental topics that appear to be closely interrelated and that are the main factors in determining the physical and mental status of an individual or a community. Air, sunlight, clothing, exercise, rest, food cleanliness, and order form the basic subjects that in the aggregate, with adequate discussion, constitute hygiene.

Society as a whole is built up of various units, all of which may be resolved into individuals. In the consideration of a method of approaching the subject so as to secure the greatest effectiveness for the teacher or the scholar, a synthetic method is far more valuable than an analytic method. To grasp the relation of personal hygiene to the health of the family is a stepping stone to an intelligent conception of the relation of individual hygiene to the health of a group of families such as would constitute a neighborhood.

Further extension of the same principles of personal hygiene is involved in the understanding of the particular problems that are indissolubly connected with the city. The State, the nation, the world are three greater syntheses of a small social unit, the individual. Thus society may be regarded as a series of concentric circles, possessing the individual as a common center. The outermost circumference embraces all the other circles, though the area involved consists of an aggregate of individuals whose various combinations are delimited by the several lesser circumferences.

If one regards the few basic hygienic factors as centering in the individual and going therefrom in direct lines there appears at once a simple system for the instruction of the young or the old in the general scheme of social hygiene. A careful and intelligent study of the laws of hygiene as they affect the individual leads to an intelligent appreciа-

tion of the relation of hygiene to civilization and organized society.

In an outline to cover various grades of the public school it is essential to get the bulk of the hygienic material into the curriculum during the period of time for which the maximum number of children are at school. This makes it necessary to grade a course in hygiene so that the main elements are disposed of before the sixth grade. The continuation of the development of hygienic themes is to be found in the upper grades of the elementary school and might well be carried throughout the secondary schools.

It is unnecessary to go further in the development of our program. I believe the suggestion is clear without further elaboration. The plan in brief is to consider the evolution of hygiene in an elementary school upon the basis of the evolution of society and to so arrange the information to be given to the children that it is adapted to their age, grade, and experience, while at the same time the course is naturally developed from a single point of view instead of being thrown into a curriculum without plan or thought and too frequently left to the discretion of the teacher. The importance of correlating all the topics in hygiene to natural history, geography, civics and economics is not to be overestimated.

If public schools are to prepare for citizenship, it may be recognized that a citizen who is conscious of his hygienic duties and sanitary responsibilities is of far greater value to a community than one who is brought up in ignorance of these important topics. The main feature that we would call attention to is that hygiene is taught as a subject by itself and the physiology is drawn in as it were through a discussion of the hygienic problems, instead of appearing as a formal subject on the program. Anatomical details are entirely omitted inasmuch as to the child in the elementary school they are of no value theoretically or practically, save in so far as they have some relation to his everyday life. In the highest grades it might be desirable to take up the subjects of anatomy and physiology as formal studies, but in that case the perspective will be practically hygiene and the interest of the children in the subject will be enhanced, whereas under the present system it is merely a test of memory.

The social hygiene instruction practically is constituted from the educational content of the various subjects already on the curriculum. It is necessary to correlate history, civics, domestic science, physical education, geography, and similar subjects so that they all bring to social hygiene their proper betterment of the hygienic conditions of the community in which children grow to become citizens.

## THE CLINICAL EXAMINATION OF THE FECES.

By ALBERT F. R. ANDRESEN, M.D.,

BROOKLYN, NEW YORK.

GASTROENTEROLOGIST, BUSHWICK HOSPITAL, POLHEMUS MEMORIAL CLINIC AND BROOKLYN HOSPITAL DISPENSARY.

The examination of the feces is in many respects as important from a diagnostic standpoint as is that of the urine, yet in this country we see very little of this work done. It is, as a rule, only the specialist who makes these examinations, the general practitioner considering his duty done when he gives a casual glance at a stool occasionally saved by the person nursing a bed-ridden patient. The excuse often given by physicians for not examining the feces is that esthetic patients object to bringing stools to the office. When the importance of this examination is explained to them, I have yet to find patients who will refuse to bring the small amount of stool necessary. Most physicians of the present day have facilities for the examination of urine, so that the addition of a very few reagents will suffice for making a simple stool examination which will often be a valuable aid to diagnosis.

The feces are most advantageously studied after special diets, but even on an ordinary diet much can often be learned. The stool of a healthy person on a general diet consists of (1) the indigestable remnants of the food, such as cellulose, bone, cartilage and elastic tissue, seeds, etc., (2) the unabsorbed portions of the food in varying amounts, (3) large numbers of bacteria, and (4) the secretions poured into the intestinal tract, viz., the bile, traces of pancreatic and intestinal secretions, and epithelial cells. Mucus is normal in moderate amount only. Abnormal elements are blood, pus, parasites and their eggs, and particles of connective tissue.

*Macroscopic Examination of Feces* (general diet).—*1. Consistency and Form:* Normal, firm, soft, and sausage shaped, or, after large quantities of fats or vegetables, mushy.

Liquid, diarrheal stools may be due, according to Klemperer, to (1) increased peristalsis from (*a*) nervous irritation, fright, fear; (*b*) chilling of the body; (*c*) the presence of irritating substances in the alimentary canal, such as ptomaines, fermenting foods, or insufficiently digested foods, as in achylia gastrica; (*d*) the presence of specific organisms causing inflammation of the bowel, such as the Shiga bacillus, the cholera vibrio, etc.; (*e*) ulcerations of the mucosa, from chronic catarrhal colitis, amebic dysentery, typhoid fever, tuberculosis, or syphilis; (*f*) the presence of toxic substances in the blood, as in uremia, and also in various infectious diseases and carcinoma. (2) The insufficient absorption of the chyme, due to degeneration of the bowel mucosa. Several of the above-mentioned causes also act in this way, but the particular causes of this condition are: (*a*) amyloid degeneration of the bowel mucosa, (*b*) stasis of the portal circulation (cirrhosis, etc.), or of the systemic circulation (uncompensated heart lesions). The stasis also leads to catarrh, placing it also in the other groups. (3) Exudation of fluids into the bowels, as in many inflammatory and infectious diseases. Diarrhea of short duration may be due to psychic disturbances, chilling of the body, and acute gastrointestinal catarrh. More chronic diarrhea occurs in portal stasis and cardiac insufficiency, in toxemias and bacteriemias, as in uremia and typhoid fever, in chronic enteritis, amebic, tuberculous, or syphilitic ulcers, and in amyloid degeneration. Tuberculosis is usually secondary to other tubercular foci, amyloid degeneration occurs in phthisis, syphilis, malaria, or chronic suppuration.

Dry, hard, constipated stools may result from (1) bad habit—insufficient exercise, improper diet (one containing an inadequate amount of residue and of water), or disregarding of the call of nature to stool; (2) intestinal stasis from atony, ptosis, or kinking of the bowel.

Goat stools, consisting of numerous small, round

masses of feces, are usually due to spasms of the bowel musculature.

Narrow, flattened, ribbon-like stools indicate obstruction, as in benign or malignant stenosis, in hypertrophied prostate, or any pressure on the large bowel from without.

II. *The Color.*—Normal, on a mixed diet, is brown, varying from a light brown on a diet rich in fats, to a dark brown or almost black after vegetables, berries, etc. Various medicinal substances cause changes in the color of the stool. Iron, manganese, bismuth, and lead give black stools; rhubarb, senna, and santonin, yellow, and calomel, greenish stools.

Clay-colored, fatty stools are seen in obstruction to the common bile-duct from any cause. Very fatty, light-colored stools occur in pancreatic disease.

Rice-water stools are typical of cholera, pea-soup stools are described as typical of typhoid fever.

Blood in the feces changes their color according to the origin of the blood. Swallowed blood, or blood from gastric or duodenal hemorrhage produces black, tarry stools; blood from hemorrhage in the large bowel is bright red and more or less mixed with the stool, according to the distance of the bleeding point from the anus. The stool of amebic dysentery is liquid, with many small particles of mucus stained grayish-red by blood, and containing some streaks of blood, whereas the feces in a case of rectal carcinoma or bleeding hemorrhoids may be merely streaked with blood on the surface.

Pus may be in streaks or mixed with the feces and gives a very foul odor to the stool.

Mucus may occur as small flecks of white translucent jelly, or as long, flat strips or cylinders of the same substance. Mucus is pathological in excess only. The cylinders and membranous pieces are seen in mucous colitis.

III. *Odor.*—The normal odor is due mainly to indol and skatol. Vegetable or milk diet produces very slight-smelling stools. Rapid passage through the large intestine, by preventing fermentation, as in cholera, produces more or less odorless stools.

A foul, putrid odor is due to proteid decomposition, which may result from too long retention in the bowel, or to the presence of excessive numbers of putrefactive organisms. The presence of blood or pus also causes a foul odor, and in the absence of bile, stools are particularly foul, because of the loss of the antiseptic action of the bile.

A butyric or acetic odor is present in diarrheal stools which are undergoing carbohydrate fermentation.

IV. *Abnormal macroscopic elements,* in addition to those already referred to, are: (1) Parasites—round worms, pin worms, and segments of tape worms; (2) gallstones and enteroliths; (3) undigested food-particles. These elements may be recognized by rubbing in a mortar or by diluting with distilled water and passing through a sieve.

*Microscopic Examination.*—On a general diet, microscopic examination of the feces is of definite value only in determining the presence of blood, pus, mucus, and of parasites and their eggs. The various forms of tape worm usually proclaim their presence by discharging segments in the feces, but their eggs are characteristic, and the microscope is often needed to identify the head. The microscopic examination is of particular value in the presence of round worms, which may be passed spontaneously only at long intervals, but whose eggs are almost constantly being discharged.

The *Entameba coli,* the specific cause of tropical dysentery, is found in stools which have been kept warm, specimens of the stool to be examined being placed on a heated slide. The amebæ die rapidly when exposed to cold, and are then difficult to distinguish from leucocytes. They are distinguished when alive by their ameboid movements and by their frequently enclosing red blood-cells in their bodies.

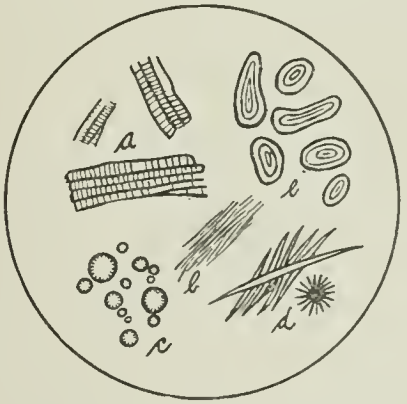
The microscopic examination will be further discussed under the next heading, the findings being of more value after a regular prescribed diet.

*The Schmidt Test Diet* is a form of diet used to get a standard on which to base the findings in examination of stools. An initial cathartic is given, and then the diet is followed for three days, a soapsuds enema being given every day if necessary. The diet is as follows: *Breakfast:* 1 pint of milk, or, in case of diarrhea, 1 pint of cocoa, made of 1 tablespoonful of cocoa, ½ tablespoonful of sugar, a small cup of milk, and water to 1 pint. *In forenoon:* One-half of the following gruel: 3 ounces of oatmeal, boiled with water and a little salt. To this add 1 pint of milk, 2 eggs, 1 tablespoonful of butter. *Lunch:* ¼ pound chopped beef, salted to taste, and superficially fried in 1 tablespoonful of butter, so that it remains raw inside; 1 large plate of mashed potatoes in which a small cup of milk and ½ tablespoonful of butter have been stirred. *In afternoon:* As at breakfast, milk or cocoa. *Supper:* Remainder of gruel. In addition to this there are to be taken, through the day, 12 zwieback crackers.

The light-colored stool of the third day is to be saved for examination.

I. *Macroscopic Examination.*—(1) Consistency, color, odor, and admixtures are observed as described under general examination. (2) Some of the stool is rubbed up with distilled water in a mortar, which will disclose calcareous particles. Some of this liquid mixture is then poured out on a black plate, when we may distinguish remnants of meat and connective tissue, mucus, parasites, gallstones, etc. The various suspicious particles are then removed and placed on slides and examined microscopically.

II. *Microscopic Examination* of the slides prepared as above, diluted with a little normal salt solution if too thick. We must distinguish: (Fig. 1)



(1) Muscle-fibers (*a*) normally present in moderate amount. If in large masses, grouped together, they indicate insufficient stomach digestion, the gastric juice being essentially the agent dissolving the connective tissue between the fibers. If in

large numbers, isolated, they indicate insufficient digestion in the small intestine. (2) Connective tissue fibers (*b*)—large numbers have same significance as large numbers of muscle-fibers. (3) Fat-globules (*c*) and needles, and fatty acid crystals (*d*), normally present in small amount are increased in pancreatic disease, common bile-duct obstruction and intestinal catarrh. (4) Potato-cells (free starch granules) (*e*) and clostridia (a fermentation product of the cellulose starch envelope) are best distinguished by putting a drop of Lugol's solution at the edge of the cover-glass and allowing it to work its way slowly under it, the starch and clostridia being stained blue by the iodine. Their presence always indicates intestinal catarrh. (5) Eggs of parasites—described above. (6) Bacteria. The study of the bacteria of the intestinal canal is intensely interesting, but cannot be discussed in an article of this scope. They are studied by simple staining and by cultural methods. Bassler has demonstrated the value of introducing cultures of the normal intestinal bacteria into the bowel in certain intestinal diseases. (7) Blood, pus, mucus, and portions of malignant tissue have a significance of their own, as described above. (8) Plant-cells occur in many forms, and are often a cause of confusion. They are usually symmetrical in form, and have a glistening, highly refractive enclosing membrane.

III. *Chemical Examination.* — (1) *Reaction:* Normal, with litmus paper, weakly acid or alkaline. Excessively acid reaction indicates carbohydrate fermentation, excessively alkaline reaction, proteid fermentation. The fumes from a portion of feces boiled in a test-tube will color litmus paper red when butyric or acetic acid is present—carbohydrate fermentation.

(2) *Schmidt's Sublimate Test.*—A portion of the feces the size of a pea is rubbed with a few drops of a concentrated solution of bichloride of mercury (2 to 5 per cent.), put in a covered watch-crystal, and set aside at room temperature. At the end of six to twenty-four hours the production of a red color is normal, indicating the presence of normal bile-pigment. A green color, even of microscopic portions, showing the presence of bilirubin, is abnormal, indicating the presence of intestinal catarrh. Absence of any color indicates common bile-duct obstruction.

(3) *Fermentation Test.*—A portion of well-stirred feces the size of a walnut is put into a fermentation tube in an incubator. If after twenty-four hours more than one-third of the water has been displaced and the reaction is strongly acid, an abnormal degree of carbohydrate fermentation in the intestine is indicated.

*A Meat-free Diet,* meaning a diet entirely free from blood, that is, total abstinence from meat, meat-soups, meat extracts, etc., for three days, is necessary before a test for *occult blood* in the feces is done. Neither should any gastric or esophageal instrumentation, such as passage of a stomach tube or bougie, be done for three days, to avoid even a slight bleeding from these causes. After ruling out the possibility of swallowed blood and blood from hemorrhoids, fissure or fistula in ano, we may conclude that the finding of occult blood in the stool is due to gastric or intestinal bleeding. Frequently blood is found in stools the color of which would occasion no suspicion of its presence. In slight bleeding from a gastric or duodenal ulcer, the stools may be light in color, but occult blood may be found.

Three tests for occult blood are in general use—the guaiac, aloin, and benzidin tests. The benzidin test requires considerable care to obtain accurate results, and is considered by some authorities to be too delicate, disclosing the presence of even the faint trace of blood which might result from the trauma of the food in the intestinal canal. The guaiac and aloin tests are done as follows: A portion of feces the size of a pea is rubbed up with a few drops of glacial acetic acid and placed in a test-tube. A few c.c. of ether are then poured on top. After gentle agitation for a few minutes, the acetic acid-ether extract is decanted into another test-tube, and a few drops of a freshly made alcoholic solution of guaiac or aloin added, together with a few drops of old oil of turpentine. The mixture is shaken thoroughly, and after a few minutes a blue color is produced in the guaiac test, a red color in the aloin, if occult blood be present. The blue color of the positive guaiac test appears more rapidly than does the deep red of the aloin test, but the latter is much more permanent.

*Tests for Ferments.*—The diagnosis of pancreatic affections, which has in recent years aroused considerable interest, is often greatly aided by certain tests for the presence of the pancreatic ferments in the stools. An absence or diminution of trypsin or amylopsin in the stools would point to pancreatic insufficiency or obstruction. The tests for these ferments in the stools require considerable time and skill, and their value is as yet in some doubt, so that their consideration in a paper of this scope would hardly be advisable.

This brief outline for the clinical examination of feces will, I hope, have some effect in interesting and aiding my readers in the study of an excretion which is often overlooked and often would reveal a long-suffering patient's true condition, resulting in a clear prognosis and rational, efficient treatment, and redounding to the benefit of the patient and the credit of the physician.

889 Union Street.

---

**Action of the X-Rays Upon the Eosinophiles.**—C. C. Aubertin states that the irradiation of the hemopoietic organs in a person presenting a pronounced degree of eosinophilia causes an immediate leucocytosis that lasts for several hours. This is not, as in the normal subject, a pure polynucleosis; it consists in an increase of the pre-existing eosinophilia to which is added an increase in the number of neutrophiles.—*La Presse Médicale.*

**Urethral Folliculitis.**—Georges Luys states that the inflammation of the glands of Littré in the course of a gonorrhea, if more or less pronounced, is called a folliculitis. This complication is very common and the abuse of injections appears to be the most frequent cause. The treatment consists in slow and methodical dilatation of the penile urethra, followed by direct endoscopic treatment. This is superior to external surgical excision. Inspection of the urethral mucosa reveals the site of the lesions which may be evacuated similarly to ordinary furuncles by incision and pressure. This method obviates the production of a urinary fistula, and the cure is complete and permanent.—*La Clinique.*

**Prognostic Significance of the Atropine Reaction in Cardiac Diseases.**—J. E. Talley notes that the atropine reaction in the normal heart is probably from 30 to 40. A reaction of 20 or less, in a heart not recently subjected to exhausting disease, points to a degenerative process in the cardiac tissue which makes the outlook for improvement under treatment unpromising. Cases of auricular fibrillation with responses normal or above are promising subjects for treatment. Two atropine reactions in cases of auricular fibrillation, one before and one on full digitalis, enable us to determine whether the vagal or the cardiac tissue factor is the greater. The patients with a large cardiac tissue factor are the ones who usually are sufficiently improved by treatment to return to their occupations.—*American Journal of the Medical Sciences.*

## AN IMMUNITY REACTION IN PELLAGRA.

WITH the increase in the work on pellagra has come apparently a diminution in the number and enthusiasm of the adherents of the zeistic theory of the etiology of the disease. The antizeists, however, are not agreed among themselves but have advanced several hypotheses which are in accord only in that they all list pellagra among the infectious diseases. Tizzoni has supported a so-called "infectious dietetic" theory and has described a streptobacillus which he thinks may cause pellagra in individuals subjected to certain dietetic conditions. In the course of this research he discovered a reaction in the blood of pellagrins which so far he has found to be pathognomonic. This reaction (*Centralbl. f. Bakt.*, vol. 67, p. 175) is brought about by the presence in the blood of the pellagrous patient of an antihemolysin which suppresses the hemolytic powers of the normal heterolysins.

The presence of this substance is demonstrated in the following manner: To a tube containing about 10 c.c. of ordinary bouillon, such as is used for culture media, is added 0.2 to 0.3 c.c. of serum from the patient and about two drops of fresh defibrinated rabbit's blood, the whole being mixed and placed in an incubator. In such a tube containing serum from an individual who is healthy or suffering from a disease other than pellagra, the red cells settle slowly and without agglutination, and after 24 hours there will be seen slight but definite hemolysis. If, however, the serum is from a patient suffering with pellagra, the cells sediment rapidly, forming a rather tenacious mass, and no hemolysis occurs even after ten days. This reaction takes place even if complement be added to the mixture.

Tizzoni claims that "the existence of an immunity reaction in the blood speaks for the infectious nature of the disease" and intends to investigate the hemolytic power of his streptobacillus. This claim is not above criticism. He asks us to believe that the stimulus of a bacterial lysin results in the production of an antilysin which is not specific. He apparently has not investigated the presence of an antihemolysin in the blood of patients infected with other hemolytic organisms. The presence, coincidently, of agglutinins is not explained. Tizzoni's past work, however, has been of a very high grade and it will be important and quite interesting as well to see what conclusions he finally arrives at after further investigation of this subject.

## NEW ASPECTS OF PANCREATIC ORGANOTHERAPY.

SEVERAL years ago Brieger announced that pancreatin, even when given by the mouth, will lower the abnormally high antitryptic index of the blood which characterizes certain severe diseases—cancer, tuberculosis and pernicious anemia. In a very recent article entitled "Combination Therapy of Pernicious Anemia" (*Deutsche medizinische Wochenschrift*, November 12), he announces three cases of success in treating pernicious anemia with a combination of pancreatin and arsenic over long periods of time. One patient has seemingly been kept alive for three years while in the other two cases life was greatly prolonged and made endurable. The same author is so impressed with the power of pancreatin to lower the antitryptic index in tuberculosis that he predicts as the eventual treatment of that disease a combination of tuberculin with pancreatin. His clinical results in this sphere of activity will be published in time. He recommends no attempt to protect pancreatin from the digestive fluids, merely giving the powder on the end of a knife blade.

One week after Brieger's latest announcement, Strubell made the definite statement that pancreatin tablets increase the opsonic index to the staphylococcus. This may explain some of the benefit to the nutrition of the diabetic which often follows the use of pancreatin. The number of drugs which increase the opsonic index to various bacteria is not large. Arsenic and thyreoidin (in small doses only) are two of these.

Ever since the introduction of pancreatin into medicine it has been known as a substitutive specific in total failure of the external secretion of the pancreas. This condition is so infrequent and requires such pains to demonstrate its existence beyond doubt (including metabolic studies) that the remarkable nature of the cure has escaped general attention. It is, however, every whit as convincing as the thyreoidin cures in athyreosis which are now so common. Bramwell's case belongs in this category as his patient was also a pseudocretin. The total absence of a natural pancreatic secretion was shown among other procedures by Sahli's iodoform test. The latter also proved that the pancreatin swallowed reached the intestine in active form. Several years of treatment restored to the patient the stature to which he was entitled as part of the removal of his infantilism which was believed to have been due to the suppressed pancreatic activity.

The future may witness the routine use of pancreatin in tuberculosis, in affections of the internal secretions (in addition to diabetes), and in many chronic affections with lowered opsonic index, in the latter case in conjunction with thyreoidin and arsenic.

## THE TEETH AND PULMONARY TUBERCULOSIS.

It is now well recognized that the condition of the teeth exerts a profound influence upon the health. The state of the teeth is, to a large extent, a monitor. If the mouth is in an aseptic condition then, as a rule, disease, functional or organic, is absent. while if oral sepsis does prevail, health is seldom satisfactory. This fact is at the present time fully appreciated in civilized lands and the physical well-being of a nation may be more or less correctly gauged by the mouths of its individual members. The teeth in relation to pulmonary tuberculosis is a subject which has not been widely discussed and yet it is more than probable that the condition of the teeth, gums, and mouth generally has a distinct bearing upon the incidence and progress of that disease.

In the *Medical Press and Circular,* January 8, 1912, is an article by George Thomson, in which he deals with this question of teeth and tuberculosis. Mr. Thomson is a dental surgeon and therefore, perhaps, may be regarded as a not altogether unprejudiced observer. He premises his statements by announcing that he holds the view that the prevention of dental caries will do more, directly and indirectly, towards the prevention of tuberculosis than any other measure that has yet been conceived. In considering the mouth as an area of infection it may be well to remind ourselves of certain anatomical and physiological facts as well as some of the fundamental principles with which he have to deal: 1. The mouth is lined with mucous membrane, which is continuous with the alimentary tract and forms part of it. 2. Mucous membranes are much less resistant to pathogenic bacteria than the skin. 3. Mucous surfaces near the external surface of the body possess a stronger power of resistance to certain bacteria than others. 4. For the first six months of life the mucous membrane of the mouth is continuous and intact but after that period hard structures pierce through its external surface and continue to do so at varying intervals, until adult life. There is nothing analogous to this in any other part of the body. 5. The mucosa of the mouth has certain specific functions, *e.g.* secretion of mucus which undergoes alkaline decomposition in the presence of mouth organisms, and is to be regarded as a protective agent to the teeth. 6. The mouth contains certain secreting glands, furnishing large quantities of saliva of variable quality and quantity having antiseptic as well as digestive properties and cleansing values. 7. Among civilized races from the earliest period the mouth has seldom been found to be normal and healthy, but is almost invariably affected by certain diseases, stomatitis, pyorrhea, alveolaris, or periodental disease, and dental caries, the latter by far the most prevalent of all.

Thomson argues that whether tuberculosis is due to bacterial invasion and symbiotic associations, or whether the disease may be looked upon as a general depression of vital resistances and a condition of malnutrition, the fact is the same, that dirty conditions favor the multiplication of adverse foes, and in the first case food and soil are provided for bacteria, and in the other case vital resistances are lowered by stagnation areas and infective foci. He claims that of all dirty conditions which tend to arouse the latent tuberculosis or fan its smouldering embers into flame none is so dangerous as the septic mouth and teeth.

Many writers have, of late, laid stress upon the menace of a dirty mouth, and it seems more than plausible to contend that it is a factor of the first importance in inciting and spreading pulmonary tuberculosis. In the campaign which is being so actively waged against tuberculosis in most countries, the condition of the mouth must be always considered. Although Mr. Thomson's views that the question of the extirpation of tuberculosis is mainly a question of sound teeth and a clean mouth may be deemed somewhat unduly optimistic, still few will be found to dispute the assertion that an aseptic state of the mouth is a great asset so far as preservation of health is concerned, and it may be that it confers a certain degree of immunity to pulmonary tuberculosis.

---

### Statistics of Cholelithiasis.

The subject of the incidence of chronic conditions of endemic prevalence is always of great interest, but it is on relatively rare occasions that physicians go extensively into the necessary statistical research so that certain characteristics become firmly established. Among the chronic maladies of universal interest is certainly cholelithiasis, and very recently Courvoisier of Basle has summed up the gallstone incidence in over 16,000 autopsies which cover a period of several decades (*Berliner klinische Wochenschrift,* December 23, 1912). The material reaches back to the opening of the Basle Pathological Institute, while Courvoisier's service alone extends back for twenty years. The entire figures show a constant 10 per cent. incidence in cadaver finds. The frequency increases directly with the age. Thus every twelfth male adult and every fourth female adult show stones at autopsy. This ratio of 3 or 4 women to 1 man which obtains in middle life is greatly reduced as the male adult becomes an old man. Thus between 50 and 60 one man in seven is affected, between 60 and 70 one in five, and between 70 and 80 one in four; so that in time age will offset sex. Above the age of 80 one man or woman in three presents gallstones. Basle represents a region in which the disease is very common, much more so than in Berne for example. Attempts to account for these differences are for the most part unsuccessful, as are likewise those which seek to connect the malady with other chronic affections of wide prevalence, like arteriosclerosis.

---

### Nonspecificity of Diseases Due to Anomalies of Internal Secretion.

The opinion constantly gains ground that, owing to the number and correlation of the endocrinic glands, we are no longer safe in associating special syndromes with failure or overproduction of special hormones. It is readily seen that several of these glands may be implicated together in a common disease process; that when one gland fails another may overact, or may also fail; and so on. In the

discussion of a paper of this scope by Goldstein, to which we have previously directed attention, which is to be found in the *Deutsche medizinische Wochenschrift*, January 2, Borchardt expresses his opinion that all disease of the endocrinic glands is evidence of the status thymico-lymphaticus. Increased size of the thymus is evidence of this status, as is hypoplasia of the genitals. Castration of an adult woman never leads to any disturbances of internal secretion in organs other than the ovaries. Diabetes occurs in nearly one-half of all cases of acromegaly but cannot therefore be ascribed to defective or increased internal secretion of the hypophysis. Zander mentioned the fact that in many monsters with defective development of the fore-brain (hemicephali, syncephali) there is always a hypoplasia of the adrenals. The association of intracranial hypoplasia, tumors, etc., with adiposity and hypoplasia of the genitals, is susceptible of a variety of explanations which may or may not involve speculations as to the hypophysis and pineal glands.

## News of the Week.

**Health of the Canal Zone.**—During the month of November, 1912, the total number of deaths from all causes among employees was 48, of which 32 were due to disease and 16 to violence, making an annual average death rate of 10.96 per thousand. This is a slight increase over the same month of 1911, when the rate was 9.75. The death rate among the entire civil population in Panama, Colon, and the Canal Zone was also increased during the month, being 25.46 in 1912, and 20.29 in 1911. As usual, no cases of yellow fever, smallpox, or plague originated on or were brought to the Isthmus during the month.

**Public Health Commission.**—The first meeting of the new public health commission of New York, recently appointed by Governor Sulzer, was held in New York City on January 20 at the United Charities Building, when testimony as to the necessity for reform legislation and as to the present conduct of the State Health Department was heard. It was pointed out that the present laws were inadequate in that they did not define the powers of the local health officers nor the powers of the State on matters of health, and also that the salaries paid in the department were entirely inadequate and, especially in the smaller towns, were too small to permit the securing of properly trained men for the work. Prof. C. E. A. Winslow of the College of the City of New York stated what he considered to be necessary to effect a diminution in the death rate, and Dr. Baldwin of the commission submitted a plan for the reorganization of the State department.

**Osteopaths Have Hearing.**—The New York City Board of Health on January 21 gave a hearing to the osteopaths who are urging the amendment of Section 163A of the Sanitary Code, which provided that all certificates of death must be signed by a doctor of medicine. The osteopaths contend that this section, which prevents them, of course, from signing the certificates, is a discrimination against them not substantiated by the attitude of the State in permitting osteopaths to practise. Representatives of the New York and Queens County Medical Societies appeared to protest against the change.

**The Quarantine Question.**—The conduct of the New York Quarantine Station has again been the subject of official investigation, this time by the Commission of Inquiry appointed by Governor Sulzer. The commission is divided two to one on the question of transferring the station to Federal control, the chairman being in accord with the medical profession of the State in favoring this control, the others opposing it and holding quite illogically that the direct control of the State is necessary because the volume of immigration is so great and the dangers of disease so menacing. To cover the cost of maintaining the station it is suggested that provision be made for increasing the fees charged for examination and fumigation of ships.

**Pills by the Million.**—Testifying before the Committee on Public Medicine in London recently, Sir Joseph Beecham stated that his firm sold a million pills a day, the approximate weight of those sold every year being fifty tons. He also stated that he expended a sum equal to $500,000 each year in advertising the pills.

**Plague in Adrianople.**—A dispatch received at Belgrade on January 20 reported the appearance of the plague in the Turkish garrison at Adrianople.

**Sir George Turner,** who was included in the list of King George's New Year honors, received thereby a recognition of his services as medical officer at Cape Colony, Africa. During his twelve years' service there he completed the work of stamping out the rinderpest begun by Koch, supervised the military hospitals during the Boer War, and devoted much time to work among the lepers in the asylum at Pretoria, and to a study of the disease. He is said now to have become himself a leper and to have been living in retirement in England, though he intends to return soon to South Africa to continue his work among the afflicted people of the leper colony.

**Another Ambulance Accident.**—In the triple collision of an ambulance from the Polyclinic Hospital, a taxicab, and a brewery truck, at Fifty-seventh street and Eighth avenue, early in the morning of January 22, the ambulance surgeon, Dr. G. W. Keil, and the chauffeur and extra man on the ambulance were all seriously injured.

**The Friedmann Tuberculosis Serum.**—Dr. Friedrich Friedmann, whose declaration that he had discovered a cure for tuberculosis has received world-wide attention, decided recently that it was useless to attempt longer to maintain his policy of secrecy, and on January 24 announced his intention of handing to the chief of the public health department of Berlin a tube of his serum with the request that the Government designate physicians to cooperate with him in giving the cure an exhaustive trial. It is now said, however, that he has postponed this publication of his remedy because a New York business man, interested in the promised cure on account of illness in his own family, has offered Dr. Friedmann one million dollars if he will come to this country and cure 95 out of 100 patients placed in his charge. If Dr. Friedmann cannot come to America the offer calls for the treatment of 100 patients with his serum at Saranac Lake by Dr. Lawrason Brown, the cure of 95 to be followed by the payment of a reward. The attempts of Dr. Friedmann to place himself upon a sound financial basis as a result of his promised cure have caused much unfavorable criticism.

**Courses in Tropical Medicine.**—The Harvard Medical School has recently established a new

department of tropical medicine, with Dr. Richard Pearson Strong, director of the Government biological laboratory at Manila, as its head. The department will give courses in the study and treatment of diseases of the tropics to graduates in medicine, as well as to the undergraduate students in the school. It starts auspiciously with a guarantee of sufficient funds for five years. Dr. Strong is a graduate of Yale University and of the Johns Hopkins Medical School, and has been professor of tropical medicine in the Philippine Medical School.

**Scarlet Fever Epidemic.**—Because of the prevalence of scarlet fever the schools at Sea Cliff, L. I., have been ordered closed for two weeks, the public library having been closed some days previously.

**Deaths of 1912.**—During the past year the death rate in New York City was 14.6 per 1,000 of population, the lowest recorded in the State's history. The total number of deaths was 5,000 less than in 1911. There were large decreases in the number of deaths due to typhoid fever and tuberculosis, as compared with the figures of preceding years, the total in the latter case falling from 14,200 in 1911 to 13,600 in 1912; and a low record for deaths due to diphtheria was made. The death rate from cancer, however, was slightly increased. Of the less usual diseases, one death was ascribed to leprosy, two to pellagra, five to rabies, five to glanders, and 100 to tetanus. Infantile paralysis caused nearly two hundred deaths.

**Death of Brother Dutton.**—News was received here recently of the death at Molokai of Ira Barnes Dutton, who for nearly twenty-seven years had served among the Hawaiian lepers. Brother Dutton succeeded Father Damien in his work in the leper settlement.

**X-Ray Injuries.**—In Chicago on January 19 a verdict for $10,000 was awarded to a woman patient against a practitioner of that city, the plaintiff declaring that her face had been disfigured and her eyesight impaired by burns due to the use of X-rays to remove a mole without proper protection of the rest of the skin. The case will be appealed by the physician.

Director Simon of the Radiographic Institute at Geneva, Switzerland, must, it is reported, undergo amputation of his left hand owing to injuries by the X-rays. His colleague, Dr. Leroyer, is said to have lost two fingers also.

**Saving Infants.**—That 300,000 babies die every year in the United States and that half of them might be saved by proper care is stated in the first publication of the Children's Bureau at Washington The bureau calls for proper birth registration laws in all the States, which would make it possible to trace all infants and give assistance through physicians, visiting nurses, and social workers to those born under adverse conditions. A model registration law has been drafted.

**To Reorganize Medical School.**—Pending a reorganization of the Medical Department of the University of Minnesota, every member of the faculty of the school on January 15 handed his resignation to Dean Wesbrook to be presented to the president of the University when the plans are completed. On the same day the Board of Regents of the university appointed a committee consisting of Dean Wesbrook; Dr. Charles L. Green, Minneapolis; Dr. L. D. Wilson, Rochester; Dr. E. L. Tuohy, Duluth; Dr. Theodore W. Bratrud, Warren, and President Vincent of the University, to prepare plans for the reorganization. In its growth the medical department has absorbed the St. Paul Medical College, the Minnesota Hospital College, and the Medical Department of Hamline University, and had thus developed a faculty much too large for the best work. The move toward reorganization is heartily supported by the members of the present faculty, who will continue their work as outlined through the remainder of the year or until the new scheme is ready to be put into effect.

**Vaccination Not Desired.**—In Philadelphia three persons were recently placed under police guard in one of the large apartment houses because of their refusal to submit to vaccination by the health authorities, and a quarantine of eighteen days was ordered. Two cases of smallpox in a negro settlement in the center of the city led to the vaccination of 6,000 people within three days, the patients being removed to the Municipal Hospital.

**To Honor Dr. Freer.**—A model of a bust and tablet to be erected at the University of Manila in memory of the late Dr. Freer has recently been completed in Berlin. The tablet is of stone with relief figures in bronze, representing "Science Aiding Humanity and Future Generations." Science is symbolized by a woman holding out a healing draft to Humanity, represented by a mother with Posterity, a sick child, in her arms. This acts as a background for a life-size bust of Dr. Freer. The work is executed by Miss Kühne Beveridge, an American sculptor.

**Dr. Kunitzer and the County Medical Society.**—At the meeting of the Medical Society of the County of New York on Monday of this week a vote was taken on the motion to expel Dr. Robert Kunitzer of the Sydenham Hospital on the charge of having permitted the falsification of the case records of the hospital by Dr. Ewald. The attendance at the meeting was very large and the discussion was protracted into the morning hours; the final vote was short of the necessary three-quarters, so Dr. Kunitzer retains his membership in the County and State Societies.

**Smuggling Drugs to Convicts.**—A new use for picture cards has been developed recently, a discovery of the fact being made accidentally by one of the keepers at Sing Sing prison, who, while sorting the prison mail, dropped a weight upon one of the heavily embossed cards much favored by the friends of the convicts. A fine white powder emerged from under the embossed figures which proved to be cocaine, and an investigation of other cards of the same type revealed the same condition. It is believed that this find clears up the mystery of how the inmates of prisons have been able to secure drugs, such as opium, morphine, and cocaine, in spite of the vigilance of the officials, and that it will not be possible for a time at least to shut off the supply.

**Down with Mosquitos.**—A conference on the subject of mosquito prevention in and about New York is shortly to be called by Commissioner of Health Lederle, whose requests for appropriations to carry on the work of exterminating mosquitos in all the boroughs of the city were refused by the Board of Estimate. The residents of Westchester County had prepared to do considerable work in draining swamps, etc., but as many of the swamps extend southward into New York City no good results will be achieved unless the city does its share. It is hoped that some plan of interesting the land owners to clean up may be evolved.

**Gifts to Charities.**—The Brockton Hospital of

Brockton, Mass., receives a bequest of $40,000 by the will of the late Horace Williams Howard of that city, who made a further bequest of $185,000 for the establishment in Brockton of a home for aged men.

**The Harvey Society.**—The postponed lecture by Major F. F. Russell on "The Prevention of Typhoid Fever" will be given at the New York Academy of Medicine on Saturday, February 8.

**Hospital Gift Withdrawn.**—The Sinking Fund Commission of New York decided recently to reconsider its transfer to the Hahnemann Hospital of title to the block at Park avenue and Sixty-eighth street for $5,000. This transfer of the city's rights worth several hundred thousand dollars was made four years ago, the understanding being that the hospital would care for the poor. The commission believes that this agreement has not been kept, and the mayor has appointed a committee of three to investigate.

**The North Carolina Board of Medical Examiners.**—The date of meeting of the North Carolina Medical Society having been changed, it becomes necessary to change the date of meeting of the Board of Medical Examiners from June 10 to June 3, 1913.

**Philadelphia Medical Club.**—On the evening of January 17 the club was honored by a visit from President Taft, who delivered an address to the members. Officers for the ensuing year have been elected as follows: *President,* Dr. James C. Wilson; *Vice-Presidents,* Dr. Wilmer Krusen and Dr. McCluney Radcliffe; *Secretary,* Dr. William S. Wray; *Treasurer,* Dr. Lewis H. Adler, Jr.

**New York Neurological Society.**—The following officers were elected for the year 1913: *President,* Dr. Smith Ely Jelliffe; *First Vice-President,* Dr. E. G. Zabriskie; *Second Vice-President,* Dr. E. W. Scripture; *Corresponding Secretary,* Dr. J. Ramsay Hunt; *Recording Secretary,* Dr. C. E. Atwood; *Councilors,* Drs. Dana, Starr, Sachs, Fraenkel, Kennedy.

**The Guild of St. Luke.**—At a meeting of this society of physicians of the Catholic faith, to be held at 120 West Fifty-ninth Street on Thursday, February 6, at 8.30 P. M., the subject for discussion will be: "How Much of Eugenics Is Scientific?" Those interested may obtain cards of invitation by addressing the president, Dr. Charles E. Nammack, 42 East Twenty-ninth Street, or the secretary, Dr. James J. Walsh, 110 West Seventy-fourth Street.

**Federation of State Medical Boards.**—The annual meeting of the Federation will be held at the Congress Hotel, Chicago, on Tuesday, February 25, 1913, under the presidency of Dr. Arthur H. Brown of New Orleans. Particulars may be obtained from Dr. George H. Matson, secretary-treasurer, State House, Columbus, Ohio. An invitation to attend the meeting is extended to all members of State medical examining and licensing boards, to teachers in medical schools, to delegates to the Council on Medical Education of the American Medical Association, and to the Association of American Colleges.

**A Society for the Advancement of Clinical Study** has recently been organized in New York City, the purpose of which is to maintain a bureau of information which will furnish to resident and visiting physicians definite information regarding the clinical facilities of the hospitals and laboratories of the greater city. For this purpose a bulletin board has been installed at the Academy of Medicine, 19 West 43rd Street, in charge of a special clerk who will be on duty between the hours of nine and six to answer all telephone inquiries (Telephone 974 Bryant). The bulletin board will consist of two sections, on one of which will be posted month by month, the regular clinics, medical and surgical, and also laboratory demonstrations, all of which are held at stated hours. The second section will include full announcements of daily operations and demonstrations of cases both medical and surgical, which as far as possible will be announced on the day preceding their performance. It is believed that these facilities will afford physicians, who are interested in observing particular operations and operators or clinicians, an opportunity to obtain the desired end with the least trouble. It is hoped that by this means the large and unexcelled clinical facilities of New York City will be made more accessible to those who may desire to make use of them.

**The DeRoaldes Prize.**—A prize consisting of a gold medal is offered by the American Laryngological Association for the best essay upon some subject relating to laryngology and rhinology, preferably containing suggestions of practical value resulting from original work. The competition is open to all practitioners in regular standing in the United States and Canada. The essays must be typewritten in English and be accompanied by a sealed envelope containing the author's name and the title of the paper. They must be sent to the secretary, Dr. Harmon Smith, 44 West Forty-ninth street, New York, before May 1, 1913.

**Obituary Notes.**—Dr. Ernest Palmer of Brooklyn, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1879, a member of the American Medical Association, the New York State and Kings County Medical Societies, the Associated Physicians of Long Island, the Society of the Alumni of St. Mary's Hospital, and the Brooklyn Gynecological Society, consulting gynecologist to St. John's, the Kings County, and the Jewish Hospitals, Brooklyn, and clinical professor of gynecology and attending surgeon at the Long Island College Hospital, Brooklyn, died at his home on January 20, aged 63 years.

Dr. Frank L. McKee of Wilkes-Barre, Penn., a graduate of the Bellevue Hospital Medical College, New York, in 1882, and a member of the American Medical Association and the Pennsylvania State and Luzerne County Medical Societies, died at his home from appendicitis, on January 13, aged 52 years.

Surgeon Francis W. Mead of the United States Public Health and Marine Hospital Service, in charge of the United States Marine Hospital at Vineyard Haven, Mass., a graduate of the Georgetown University School of Medicine, Washington, in 1858, and a member of the American Medical Association and the Massachusetts State and Dukes County Medical Societies, died at the hospital on January 18, aged 74 years.

Dr. Willard H. Titus of Oshkosh, Wis., a graduate of the Hahnemann Medical College and Hospital, Chicago, in 1873, a member of the Wisconsin State and Winnebago County Medical Societies, and an expert in Indian ethnology, died at his home on January 8, aged 65 years.

Dr. Richard C. Allen of Philadelphia, Penn., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1868, died at his home on January 19, aged 84 years.

## Correspondence.

### OXYGEN IN THE TOXEMIA OF PREGNANCY.

To the Editor of the Medical Record:

Sir:—In your issue of January 25 Dr. S. J. Druskin, referring to my article on oxygen in the toxemia of pregnancy, says: "The injection of oxygen under the breasts in eclampsia is not altogether new or unknown." This is true. Not only was it so used by Wertheim, as Dr. Druskin recalls, but it has also been used by Dr. Espy M. Williams of Patterson, La., and (in cattle) by Healy and Castle of the Kentucky Agricultural Experiment Station. In all these cases, however, the oxygen was used in order to isolate or destroy some hypothetical toxin generated in the breast.

On the other hand, the experiments which I conducted at the City Hospital were made, not upon cases of eclampsia, but upon cases of pre-eclamptic toxemia. They were not based upon any theories about the mammary secretion, but, as I expressly stated, upon the definite hypothesis that suboxidation plays a large part in the etiology of the so-called toxemia of pregnancy. It was to the systematic and continued use of oxygen in toxemia with the idea of preventing eclampsia, and not to the occasional or empirical use of oxygen in eclampsia proper, that I referred, when I said, "I have found no reference in English, French, or German, to the use of oxygen in the toxemia of pregnancy." The distinction is perfectly clear.

In addition to the free use of oxygen either by inhalation or subcutaneously, I would advise the use of iron, calcium oxide, and other oxygen carriers; and of alkalies to combat the acidosis that is so constant an accompaniment of incomplete oxidation. It is interesting to note that these agents have been found useful on different grounds and by different observers. Dr. John A. McGlinn of Philadelphia, in a recent article, emphasizes the importance of keeping toxemic patients out-of-doors, and states that he has obtained good results by having his patient sleep in the open air, following the lines of the modern treatment of pneumonia. This, too, is significant.

In pregnanc· the whole organism cries out for oxygen. Who has not noticed the subjective dyspnea so common even in cases approximately normal? What observant physician is unfamiliar with the bad effect of stuffy and ill-ventilated rooms, and with the relief afforded by the open window?

What can be done in the treatment of eclampsia proper? Healy and Castle have reduced the mortality in cattle to a very low figure, but it remains to be shown that the disease is as malignant as in the human subject. Dr. Williams treated his case on the theory that the toxin is a mammary product, but shrewdly observes that it is unlikely that we can shut off the blood supply of the breast by the injection of oxygen, and thinks that the effect may be due "to a direct action of the oxygen on the toxins themselves." He notes that although the distention of the parts was extreme, extending even up to the clavicles, the absorption of the gas was very rapid.

Without doubt the preventive treatment of eclampsia will always be more satisfactory than the curative, but even here the oxygen treatment is rational.

George P. Shears, M.D.
203 West One Hundred and Third Street.

### OUR LONDON LETTER.

(From Our Regular Correspondent.)

INSURANCE CRISIS—MEETINGS, ETC.—HEART DISEASE IN CHILDREN—KEITH ON NAPOLEON'S DEATH AND ALLEGED SPECIMENS—OBITUARY.

London, January 10, 1913.

London practitioners have spoken. On Tuesday about 1,500 met and denounced the "unfair methods of intimidation" used for "coercing" them to go on the insurance panels. Probably never before has such a high pitch of feeling been expressed by the profession. Our late medical lord mayor, Sir T. B. Crosby, an octogenarian practitioner, presided, feeling in doing so he was as he had been all his life loyal to his profession. Much more gratifying would it have been, he said, if he had been privileged to give thanks for a beneficial act which medical men would gladly work to complete success. The resolution of protest was then moved by Mr. E. B. Turner, who voiced in a vigorous address the indignation of the assembly, which reponded with round after round of cheers. The campaign for the Act had, he said, been carried on by deliberate lies and false statistics served up to the press morning, noon, and night. Then came downright intimidation and threats of ruin, with the Chancellor of the Exchequer rushing about like a malign comet, wagging behind him a daily lengthening tail of threats, contradictory assertions, repudiated utterances and broken promises in his determination to force a free profession into compulsory service. To carry his point he organized, to use a sporting term, "a rot" in the profession so as to set up a stampede on to the panels. Suppose the Chancellor told a body of laborers that in future they must work under government rules and at government prices or interlopers would be brought in to ruin them. Would they not hear the tramp of thousands on the march to the parks and the government tumbling down to come to terms and pass a short act through all its stages in a day or two to give them all their demands. But laborers votes counted.

Mr. Macnamara seconded the resolution, saying he would take no orders from moral lepers, who degraded the name of statesmen and begging any who had joined to recant. Mr. McAdam Eccles supported and said they were fighting for free choice of a doctor and for the honor of the profession. Mr. Boomhill and Mr. Montgomery Smith followed with caustic denunciation of the Chancellor's despotism and bribery of voters. Then amid loud cheering the resolution was carried without a single dissentient.

Every day since this meeting has brought some change in the position. The government went on steadily with their plans boasting that the panels were being rapidly filled. On the opposition side the danger of giving was urged. We were assured that for London 975 men had given their names, and yesterday there would be more than 1,000. Opponents said, "Wait and see." This morning the number agreed is 759, but the disappointment is diminished as it is declared 100 more who live on the border are willing to come in but have not yet decided in which district they will serve. These, and the commissioners boast others, too, can be brought in and, of course, will take the patients of the residents, as has happened in the country where this threat has been effectual; *e.g.* at Wisbeach only two men offered and the committee gave notice to the others that unless they joined in forty-

eight hours those two would be requested to engage assistants enough to work the locality. In another town a deputation of the profession desirous of coming to an arrangement were told "there is the Act —it will be worked. You may either work it yourselves or be ruined." The insured person may also have a say if "free choice between doctor and patient" as promised is admitted. Many have, therefore, applied to "contract out," as permitted by the Act. But to this move the commissioners reply that every applicant must satisfy the committee that there are special circumstances why he should have free choice and that the doctor he chooses must engage to fill up the same reports and certificates as those on the panel. A great number have signed the request to contract out, but it is doubtful whether they will put further pressure on the government. Several meetings are being held and others are arranged for all the coming week.

A number of practitioners who at first went on the panels to see, as one said to me, "how the cat would jump," have resigned. To meet this the officials have circulated a warning that they are liable for breach of contract. The natural reply is, prove your damages and fancy a government prosecuting any one for resigning an office.

The London Committeee of the B. M. A. has issued the long-talked-of alternative scheme. It is of interest as the opposition in the metropolis is being carried on more actively than in most other parts, and the association maintains that it will continue to oppose in every way the introduction of new men or of assistants to coerce the profession.

A discussion on the treatment of Heart Disease in Children at the Royal Society of Medicine was of special interest to me. It was opened by D. E. Cautley, who spoke of modern methods of treatment as a survival and improvement of the past consequent on the recognition of myocarditis and its results. In childhood the heart was a growing organ and age to some extent modified treatment, but happily degenerative changes were extremely rare. Functional disorders were comparatively unimportant, but in many of the cases so diagnosed the cause was myocarditis—a sequel of some infective disease. Treatment was chiefly by rest, the duration of which must be proportionate to the degree of dilatation and differing somewhat in pericarditis, endocarditis, and myocarditis, being most prolonged in the last named. Massage, active, and passive exercises, Nauheim methods and electrotherapy had their place later. Of older methods in acute inflammations Dr. Cautley found blistering distinctly beneficial in pericarditis, but of doubtful value in the other cases. Bleeding required caution in childhood. Mercury was useful if the liver became congested. The pill of digitalis, squill, and mercury was a favorite combination which had not been improved. The bowels should in all cases be kept free by mild laxatives and edema or backward pressure called for purgation. Diuretics, too, were required, aided by dry-cupping over the kidneys. In edematous cases liquids and salts should be limited. Of digitalis the tincture has rather displaced the once favorite infusion and many prefer the alkaloid preparations; others diuretin and theocin sodium acetate. Vasodilators were not needed. Morphia, aconite, and belladonna might sometimes be useful. It is still unsettled what may be the value of salicylates or iodides. Paracentesis and drainage as well as cardiectasis were also considered.

Dr. James Mackenzie pointed out that the significance of murmurs and irregularities was often mistaken. These phenomena might be compatible with healthy hearts. The cause of a functional murmur was not the cause of heart failure. This failure was always due to impairment of the cardiac muscle. The signs of the efficiency of this muscle had not been sufficiently considered and therefore the meaning of phenomena which were quite normal had been misunderstood and so not seldom taken as indications for treatment.

Sir Jas. Goodhart could not express his own opinion on the subject better than Dr. Mackenzie had done, and for forty years he had been examining these cases. On one point he did not agree with Dr. Cantley, who did not seem to think functional disease in childhood common, whereas he himself saw more cases so diagnosed in whom nothing was the matter than of those in whom there was something. Bad cases were recognized at once, but many borderland cases were thrown into the limbo of diseased hearts though there was no real disease. He had seen a child condemned to bed for weeks though nothing was the matter. The apex might have beaten in a little different position, but that varied enormously in children. A busy general practitioner was apt to be too hurried over his diagnosis and should ponder over it. Treatment was a matter of rest and the crux was how long, for it was possible to take too much—and even in definite advanced disease, too. One condition interested him much—mitral stenosis, rare in childhood, but common at 16, 18, or 20; essentially a disease of females and not congenital; or rheumatic endocardial condition leading slowly to thickening. It might be compared with urethral stricture which, before becoming serious, had been in existence a good while, the passage being kept open by the urinary stream. So in this stenosis the blood passing through the valvular apertures maintained the passage.

Dr. John Hay regarded heart disease as an infective process, probably streptococcic, beginning in childhood and leading to sclerosis and other effects in adults. Therefore prophylaxis is needed in the active stage and also in the slumbering infection with exacerbations later on. The idea that infection entered by the nasopharynx was spreading and measures directed to this should be resorted to as far as possible in every child that showed any sign of rheumatism.

Dr. Walter Carr's experience was mostly in hospitals where functional cases were not common, but acute rheumatic disease was. Rest for these was first and foremost, proportioned to the degree of carditis—more prolonged if pericarditis was also present, and most if there were nodules. In any rheumatic trouble it was safe to assume myocarditis was present. He had often seen relapses of cardiac rheumatism with pericarditis in patients while taking salicylate of soda, and mentioned one in which a boy of nine was taking 50 grains per diem and was kept at rest. In convalescence iron often disagreed and seemed to him to favor relapse. Digitalis he had never known do good. Cod liver oil not diluted or combined, was a good food ½ to 1 dram two or three times a day, and children took it well.

Dr. Sutherland protested against treatment of children in whom all activity of heart disease had passed off, leaving no symptoms. Such were often seen in the public schools and treatment supposed

to be required, but it was not and it was only desirable to prevent further rheumatic infection or strain of the heart. If a child went about its own way it would not strain its heart, but it might if compelled to do certain exercises.

Dr. Alex. Morison thought the dread of opium in childhood was too great. There was in these cases a constitutional excitement—dilated pupils, and capillaries, quick pulse—a sort of pathological belladonnaism, or physiological antidote to opium.

In cardiac infantilism one saw patients of 15 or 16 with a development of 10 or 11, very anemic and puberty delayed. He gave them thyroid as he had seen the gland atrophied post mortem and thought the laboring heart might have its activity lessened, as the gland had become exhausted. His experience of cardiectasis had not been rosy, but the principle he admitted seemed right.

Dr. Cautley in reply said that some speakers had based their remarks on adolescents rather than children. True functional heart disease in children he found distinctly uncommon. He did not mean mere irregularities. Many cases thought functional had a myocardial origin, mostly resulting from infection and must be treated by prolonged rest. No competent practitioner would say a girl had organic disease merely because she fainted.

Prof. Arthur Keith, Conservator of the Museum at the Royal College of Surgeons, has studied carefully the specimens preserved there and alleged to have been obtained from the body of Napoleon. There has been much controversy as to their genuineness in the past and it is natural to consider the opinion of such an able observer as Keith whatever one may have thought previously. One cannot forget, however, that these cancerous specimens have been pronounced not to be so by such micropathologists as Eve and Shattock. Professor Keith, in his second Hunterian lecture, gave the result of his studies of the specimens and their history and considered portions of the controversy they have provoked. They came into the possession of the college through Sir Astley Cooper, who was living at the time of the death of the captive of St. Helena. Sir Astley received them from Dr. Barry O'Meara, Napoleon's physician, a post also held by Dr. Antomarchi, who was questioned about inheritance of cancer by the Emperor, whose father died of cancer of the stomach. From his study of these specimens Mr. Keith concludes they were actually derived from Napoleon's body and throw a new light on the drama of St. Helena. They consist of small intestine with outgrowths, and though slight documents to shed light on the old vexed questions, the lecturer believes they have the advantage of other available documents inasmuch as they are documents for all time. Sir James Paget, when revising the college catalogue in 1883, described the outgrowths on the specimens as rounded plaques of cancer. Sir Astley Cooper's entry of the specimens in the MS. Catalogue of his museum is "Incipient Fungus in the Glands of the Intestine. Napoleon, Barry O'Meara to Astley Cooper." Professor Keith said his faith in the genuineness of the specimens rested on his belief that Sir A. Cooper would not have left the statement on the label unless convinced of its truth. His collection was acquired by the R.C.S. in 1841, when it was reported to the council that Sir Astley had only attached the briefest descriptions to his specimens and that full histories could only be obtained by careful search through his private papers—a search never carried out. Professor Keith thinks it is clear that Napoleon suffered from endemic fever and his liver was affected. In the course of his illness cancer supervened, but the symptoms were masked by the earlier disease. The case might well have baffled the most able physicians until the terminal illness in 1821 when the stomach was suspected to be the site of the trouble. It was still an open question whether fever or cancer was the cause of death, but it is certain that in St. Helena or elsewhere cancer would have eventually killed the great Emperor.

6. Brain Tumor. Operation. Autopsy. Findings. F. D. Bond and A. H. Peabody.

**1. Antitoxin Administration.**—W. H. Park states that in Boston the tendency is, in light cases of diphtheria, to give from 6,000 to 10,000 units, repeating if improvement does not follow; in moderate cases 10,000 units repeated every six or eight hours; in bad cases from 20,000 units to 30,000 units, repeated every six to eight hours, until a total of 200,000 or 300,000, or even 400,000 units have been given. As to the method of injection, it is noted that the subcutaneous method is the rule, and the size of the individual is disregarded. Koplik, in New York, advises a maximum of 20,000 units. In Germany Baginsky gives a maximum of about 6,000 units, and Feer of Heidelberg, 10,000. Hutinel of Paris regulates dose by age, and Ker of Edinburgh, by the intensity of the disease. From all the observations one is impressed with the belief that amounts of antitoxin beyond 25,000 units in a child, and 50,000 in an adult, are absolutely unnecessary and useless; and that an initial dose of 10,000 in a child and 20,000 in an adult is probably sufficient for the whole course of the disease. The object is to get enough antitoxin into the blood to neutralize any toxin present there, so that no further toxin is able to pass out to the tissue cells. Very few really appreciate the fact that what is given subcutaneously as a single injection is being absorbed for days, and that the accumulation of antitoxin in the blood reaches its highest point from the second to the fifth day. It should be recognized that the size of the patient is one of the important factors in deciding the dose of antitoxin. The author is of the opinion that one should give in the first dose all that is required for the entire disease. Intravenous injection is urged not only in cases of malignant diphtheria but also in all cases of tetanus.

**4. Chronic Focal Suppurations in the Head.**—F. P. Emerson points out that every infection must have some portal of entry. Bacteria do not invade normal mucous surfaces. The path of infection being by way of the lymphatics, it is obvious that one should examine carefully the glands and lymph follicles through or from which the infection must come; also the teeth and sinuses of the head. This is more important in adults than in early life in the case of the tonsillar tissue, as its resistance is lowered on account of the fact that it is the seat of a chronic hyperplasia. Also the blind closure of the crypts favors the formation of enclosed abscesses during the process of retrograde metamorphosis, when the resistance to infection

is lessened. A small amount of tonsil tissue entirely concealed behind the anterior pillar may be but the shell of such an abscess. On the other hand, it may lie deep in the space between the superior constrictor and the tonsil with only a small sinus communicating with the surface, so that the focal reaction is only manifest in the deep cervical lymphatics and pus may not be detected without grasping the glandular tissue with strong forceps.

10. The Origin of Medical Journalism. V. Greco.

1. **Superficial Metastatic Growths.**—W. W. Babcock believes that when superficial or subcutaneous nodules appear in patients who are suspected of harboring a malignant tumor, often the most direct way in which the diagnosis may be ascertained is by cocainizing the area and, by a very slight operation, removing a part or all of the nodule and subjecting it to microscopical examination. In this way one avoids the dangers that may attend the removal of tissue from the primary growth, and may prove the condition of inoperable metastasis. Obviously, superficial secondary growths are not invariably present, yet if careful search is made, superficial metastatic manifestations will be found more frequently than is suspected.

2. **Edema of the Lids.**—G. W. Vandegrift notes that edema of the lids may be inflammatory or non-inflammatory, due to conditions in the lids themselves, in the eyeball and annexa, or in the general system. Inflammatory edema may be due to: (1) Lid abscess which arises from local infection, injury, or erysipelas. (2) Chronic dacryocystitis, which, when acute, will produce an edema commensurate with the violence of infection. (3) Hordeolum or stye, an infection of a hair follicle. This is the most frequent cause of edema of the lids. (4) An acutely inflamed chalazion or Meibomian cyst produces a slight edema. (5) Periostitis of the margin of the orbit, most frequently of syphilitic origin, may produce edema of the lids. This may also be caused (6) by a furuncle. Other conditions causing edema are (7) erysipelas; (8) insect stings; (9) inflammations of the conjunctiva, iris, and ciliary body; (10) irritations of the cornea; (11) violent inflammations of the interior of the eyeball, of Tenon's capsule, abscess or tumor of the orbit, and thrombosis or aneurysm of the cavernous sinus. (12) Tarsitis, a manifestation of tertiary syphilis, is always accompanied by inflammatory swelling over the tarsal cartilage, usually of the upper lids. (13) Dermatitis from rhus toxicodendron produces usually a marked swelling when the lids are involved. Noninflammatory edema may be due to: (1) Angioneurosis, a condition that produces a transient but marked edema. (2) General circulatory disturbances as from kidney lesions, causing an edema usually of the lower lids, noticeable in the mornings. (4) Catarrhal inflammation of the accessory nasal sinuses. Certain conditions simulate edema, such as tumors of the lid, for example, dermoid cyst of the outer angle of the orbital margin. Palpation establishes the diagnosis. Emphysema may appear to be an edema pure and simple. It is due to displacement of air into the tissues of the lids from the nasal cavities through a fracture of the inner wall of the orbit, caused by a violent cough, sneeze, or blowing of the nose soon after the injury has been sustained.

7. **Cauterization in Tuberculosis of the Larynx.**—R. Pettit points out that the advantages of submucous cauterization over the old method of removal of tuberculous infiltrations by curettage, are that the former is easier to perform, requiring no more skill than that necessary in making any topical application to the larynx, and is of much shorter operation, being completed in a fraction of a minute. There is neither bleeding, in itself dangerous, nor aspiration of blood, nor coughing or struggling, nor exhaustion, symptoms seen so frequently to attend the use of the double curette; consequently the postoperative disturbance is less. In the majority of cases the curettement of an infiltrate merely means the conversion of a sluggish granuloma into a more or less progressive tuberculous ulcer.

10. **Chromoureteroscopy.**—B. H. Thomas reports the results obtained in 200 cases in which chromoureteroscopy was employed with indigocarmine as a functional test. The author prefers this test to that by phenolsulphonephthalein as not requiring ureteral catheterization and thus doing away with possible infection and the difficulties due to that method. He summarizes his results as follows: (1) Chromoureteroscopy based on the employment of indigocarmine is the most valuable single test for renal sufficiency or insufficiency because it is the most practical, affording the same diagnostic advantages as the functional tests dependent on bilateral synchronous ureteral catheterization, the technique and determination of which are tedious and complicated. (2) The test is particularly applicable in surgical affections of the kidneys and ureters, and almost invariably suffices to establish the prognosis and diagnosis, if, when the condition arises, it is supplemented by ureteral catheterization, uranalysis, collargol injection, or skiagram. (3) Comparative observations of the onset and intensity of the color elimination have never failed to determine the functional sufficiency of the supposedly normal twin organ, in view of operative intervention. (4) It is of no value in movable kidney, in the absence of ureteral kink or hydronephrosis, pyelitis, essential hematuria, early tuberculosis, and certain other forms of nephritis and small tumors not involving the major portion of the parenchyma, although ureteroscopy itself is not without value in these conditions. (5) It is of value in the differential diagnosis of hemorrhagic and chronic interstitial nephritis from other types of the disease. (6) Supplemented by ureteral catheterization and the *x*-ray it will enable one to diagnose practically every case of renal and ureteral calculus. (7) In hydronephrosis, pyonephrosis, pyelonephritis, ureteral occlusion and chronic tuberculosis of the kidneys involving approximately one-third of the parenchyma, chromoureteroscopy is of exceptional merit. (8) In simple hypertrophy and carcinoma

of the prostate causing chronic retention of urine and *vis a tergo* urinary presure on the renal parenchyma, the indigocarmine test promises to be of value in the differentiation of operable and nonoperable cases. (9) Chromoureteroscopy is also of great value in the differential diagnosis of obscure abdominal conditions; also in facilitating difficult ureteral catheterization. (10) The duration and quantity of indigo excretion are of interest scientifically and also of some diagnostic importance, but as a routine are not practicable of determination and are unnecessary of notation. (11) Indigocarmine is eliminated from functionally sufficient kidneys as a dark blue in from three to twenty minutes and as a light blue not later than fifteen minutes. In 90.1 per cent. of kidneys it appears either as a dark or light blue in fifteen minutes; in 61.1 per cent. it is observed in ten minutes. (12) If the indigo does not appear at the expiration of fifteen minutes (light blue) or twenty minutes (dark blue) one may perceive in this fact evidence of serious insufficiency of the renal function. (13) If the elimination of the dye does not occur at all the respective kidney or ureter is gravely diseased. (14) The intensity of the color reaction depends to some extent on the concentration of urine but largely on the individual excretory power of the organ. (15) A surgically diseased kidney eliminates the dye less intensely than its normal twin organ, or not at all. (16) The test is very simple, and by alternate observations of the two ureteral orifices differences between the two kidneys are readily, accurately and speedily noted.

11. **Blood Cryoscopy and Renal Function.**—M. Krotoszyner and G. W. Hartman discuss the value of blood cryoscopy as a test of renal function. Since so much stress is laid by Kümmel on accuracy and technique, they describe their method in detail and give brief description of the clinical features of interest in the patients subjected to the tests. Altogether 132 determinations were made on sixty-nine persons and the authors feel justified in formulating the following conclusions: (1) Cryoscopy of blood, done correctly, gives a point of about 0.656 C. below zero in the presence of healthy kidneys. (2) This point is not materially altered through unilateral kidney lesions, provided that the other organ is anatomically and functionally intact. (3) A lowering of the blood-point to 0.52 and lower is generally found in anemic or cachectic individuals with otherwise healthy kidneys. (4) A rise to 0.60 and above should be interpreted as a danger signal of derangement of renal function and should indicate caution against radical operative procedures. (5) In the hands of a critical observer cryoscopy of blood is a valuable test for the estimation of absolute or total renal function, especially when estimation of relative function, through ureteral catheterization, is not feasible.

15. **Poliomyelitis Carriers.**—S. Flexner, P. F. Clark, F. R. Fraser have found that the washings from the nasopharynx of the parents of a child affected with poliomyelitis, neither of whom showed any symptoms of illness and who were evidently not suffering from poliomyelitis, contained the virus of epidemic poliomyelitis. The result described brings indubitable evidence of the occurrence of the virus of the disease in the nasopharynx of healthy persons who have been in close contact with an acute case of poliomyelitis, and affords an experimental basis for the belief, based on clinical observation, of the occurrence of passive human carriers of the infection.

1. **Insect Porters of Bacterial Infection.**—C. J. Martin reviews the experimental evidence that plague is easily transmitted from animal to animal by rat fleas. In the presence of fleas, the epizootic, if started, varies as regards severity and rate of progress with the number of fleas present and the season of the year, whereas all attempts to induce epizootics in the absence of fleas have failed. Under natural conditions (experiments in plague houses, etc.) an animal can be protected from infection by any simple procedure which will exclude the visits of fleas. The only discovered infection in plague houses resides in plague-infected fleas. The rat fleas *X. cheopis* and *Ceratophyllus fasciatus* readily bite man. The conclusions drawn from animal experiments, when applied to the problem of the spread of plague amongst human beings, afford a reasonable interpretation of every cardinal epidemiological fact. As regards the transmission of typhus by lice it is pointed out that the infection of typhus circulates in the blood during and for some time after the febrile period. It is taken up by lice when they feed upon a patient and may be transmitted to monkeys by them. As in the case of fleas and plague, a considerable number of insects, ten or more, is required to give a reasonable chance of infection to a monkey, an animal which is probably much less sensitive than man. There is reason to believe that the virus proliferates inside the insect, for in order to produce infection by means of blood taken from a patient, the volume required is much larger than could possibly be contained in the lice employed. The infectivity of lice endures seven days, and seems to be greater some days after feeding on a typhus patient than immediately, but the number of experiments so far performed is not adequate to establish this. There is reason to believe that the infection may be transmissible to a second generation of lice. The present limitation of outbreaks of typhus to the most vermin-infested section of the population, its occurrence at a period of the year when the clothing is rarely removed from such persons, and washing of either takes place at considerable intervals, and the practical limitation of the disease to cold climates, all receive ready interpretation on the assumption that lice are essentially the porters of infection. Further support is provided by the non-infectivity of typhus under modern hospital conditions and the success attending prophylaxis directed towards the extermination of insect parasites, and there is no known epidemiological fact inconsistent with the view that lice carry the infection. There is really no evidence to incriminate the bedbug in the case of either typhus or relapsing fever. It is possible to transmit plague experimentally by means of bugs, but there is no epidemiological reason for supposing this takes place to any extent in nature.

2. **Colloid Tumor of the Third Ventricle.**—A. J. Hall reports a series of nine cases in which a colloidal cystic swelling attached to the choroid plexus was found lying in the anterior extremity of the third ventricle, attaining the size of a marble or Barcelona nut, and causing death either with or without definite cerebral symptoms for some time before. When fresh these tumors are soft and gelatinous and must by their physical characteristics pack closely up against the sides of the ventricle and very effectively plug the foramen of Monro. It seems probable that the process by which they have reached their final positions has been something as follows: Starting as a small tumor lying in the anterior end of one or other choroid plexus, on the floor of the corresponding lateral ventricle, it has in its growth followed the line of least resistance, or been pushed along with the current of cerebrospinal fluid, and gradually slipped over the inner bor-

der of the optic thalmus, into the third ventricle, pushing beneath it the velum interpositum. Until it reached such a size as to become wedged in the third ventricle probably few symptoms would arise, but with the gradual obstruction to the venous circulation through pressure on the veins of Galen, and the obstruction to the passage of cerebrospinal fluid, temporary or continued symptoms of intracranial pressure develop. In the temporary attacks of headache, as in one of the author's cases, or the more severe attacks of stupor preceded by restlessness in the case recorded by Mott and Barratt, recovery followed rest, and possibly the dorsal or a unilateral decubitus relieved the ball-valve pressure and produced equilibrium once more. In the case of Batten and Collier, and possibly also in another of the author's, the ball-valve once having come into play remained firmly fixed until death; for it seems obvious that with any increase of pressure in the lateral ventricles the sides of the third ventricle will be more tightly pressed upon the contained tumor, and it will therefore become more firmly held the more the pressure increases. In fact, once the tumor reaches its final position and a certain size everything aids its obstructive action—the more it obstructs the veins of Galen the greater will be the pressure in the lateral ventricles and so the tighter will the tumor be held; but the tighter it is held the more completely will it plug the ventricular channel.

4. **Hairpin Impacted in Ascending Colon.**—L. McGavin reports the case of a physician who while making a topical application to the pharynx with a straightened-out hairpin, accidentally swallowed the latter. The case is of some interest, not only from the unusual nature of the accident, but from the apparent ease with which so pliable and sharp-pointed a foreign body should have passed the cardiac, pyloric, and ileocecal orifices, as well as the whole length of the small intestine, without arrest. So far as the cardiac and ileocecal orifices and the small intestine are concerned, this must be put down to its elongated character, but only good luck could have helped its five inches of length through the pylorus. Having arrived at the colon it would there have greater width in which to alter its position and so become impacted transversely. The second point of interest was the false idea given of its real direction by an excellent radiogram. In this connection it is wise to remember that the value of a radiogram of a foreign body in the intestines is chiefly limited to denoting the quarter of the abdomen in which it lies, since in a coil of jejunum lying low down it may appear to be in the cecum or the sigmoid, while in a coil of ileum lying high up it may suggest the stomach or the transverse colon; it cannot denote the actual section of bowel with any certainty. The hairpin was successfully removed at operation.

1. **The Postmortem of Napoleon.**—By A. Keith. (See page 212.)

2. **Insect Porters of Bacterial Infection.**—By C. J. Martin. (See page 214.)

3. **Medicine and Liberty.**—W. Gordon notes that there have been four great periods of preeminent progress in medicine. The first was coincident with the golden age of Greek culture and culminated in the lifetime of Hippocrates, about the second half of the fifth and the beginning of the fourth centuries before Christ. The second occurred rather late in the Renaissance, and its activities centered round Padua in the sixteenth century of our era. The third followed close on the second, reaching from the seventeenth century onwards to culminate in the nineteenth, its activities centering round England. The last, which is but the expansion of the third, began within the nineteenth century, and its activities reach throughout the civilized world. If these periods be examined attentively it will be found that all of them have this salient characteristic in common, a remarkable development of intellectual and personal liberty. The first period corresponds to that wonderful epoch in which human intelligence suddenly attained to heights not since surpassed, and in which admittedly one chief cause of so great a growth was the unexampled intellectual freedom which then permeated the Hellenic world. The second period formed part of that great European revival of learning which followed the flight of Greek scholars to Italy and the invention of printing. As its activities centered around Padua, it was associated with the greatest intellectual freedom of the time, for Venice was then mistress of Padua, and in every way fostered its university, that it might worthily advance the new learning. It was under the protection of the enlightened Venetian Senate that Vesalius enjoyed those unique opportunities for the study of anatomy which enabled him, in 1543, to publish his work on the "Structure of the Human Body"—a work that broke the medical slumber of more than a thousand years, shattered the fabric of Galenical authority, and, by founding modern anatomy, made possible the construction of a new physiology and a new medicine. The third period opened with the work of another Paduan—William Harvey—who, after four years' study under Fabricius, the discoverer of the valves in the veins, took his degree in 1602, and twenty-seven years later published his immortal work on the circulation of the blood. It was in post-Elizabethan England, then practically working out an ideal of popular liberty unknown elsewhere, that he completed his investigations, and that, untroubled by Government interference, there followed him the succession of illustrious medical observers who may be said to have culminated in Lister. There is sound historical and contemporary evidence that the progress of medicine is intimately related with liberty of thought and action. Wherever lay control exceeds what is necessary, the progress and practice of medicine are impaired. The proposals now made in the British National Insurance Act are so pernicious that it is the duty of the medical profession to resist them by every legitimate means in its power.

4. **Salvarsan in Pernicious Anemia.**—E. F. Maynard states that recent reports might lead one to suppose that in salvarsan we had possibly a specific in pernicious anemia; that such, however, is not the case is unfortunately borne out by the total failure of this drug in the following instance, which is still under the author's care in the Sussex County Hospital. Why in one case the drug should bring about an apparent, if temporary, cure, and in another totally fail to produce any improvement remains for the future to elucidate. C. H., aged sixty-one, stated that he had not been fit to work for two years; that he had had indigestion and jaundice, had lost weight considerably, and had vomiting and diarrhea, headache and drowsiness. His skin was bronzed on face and hands, but there was no pigmentation of mucous surfaces, nor around the nipples. The heart and lungs were normal. He was at first thought to be the subject of Addison's disease, but a blood examination negatived this diagnosis, and showed the condition to be pernicious anemia. The temperature was never as high as 100° F., but invariably at night ranged between 99° and 100°; on the night following the first injection of salvarsan it was somewhat higher, but ever afterwards distinctly lower, never reaching above 99°. He was admitted October 3, 1912. The first dose of 0.3 gram of salvarsan was given intramuscularly on October 13, after which there was a definite increase in

the number of red cells for a fortnight, when a second dose of the drug was given (October 29). Examination of the blood a week later revealed a diminution in the red cells; the treatment was therefore stopped. The patient has since November 30 been treated with an autogenous vaccine of a pure culture of streptococci obtained from the gums, and the latest report shows some improvement in the number of red cells, and the color index, and fewer normoblasts and megaloblasts.

### Berliner klinische Wochenschrift.

*January* 6, 1913.

**Foundations of Drug Therapy.**—Heffter writes briefly on this subject, going back to the period at which the *Wochenschrift* was first established by Posner, just fifty years ago. At that epoch therapeutic nihilism had been overcome, but our exact knowledge was as yet very slight, consisting chiefly of "supporting measures"—the reinforcement of weakened physiological processes. The profession seeks always for specifics and for treatment based on causes. As far as the latter is concerned our only attainments were in the treatment of poisonings. If we knew the poison to give its antidote was of the nature of causal therapy. The latter subject sprang into generalized existence with the discoveries of Lister and Koch, although internal disinfection lagged far behind the external form. Quinine cured malaria on the principle of internal disinfection, but, of course, this was not understood for years. At present Ehrlich and his disciples are making great advances in this field. In the competing field of serotherapy we also see the operation of causal therapy—the so-called etiotropic medication. The old physiological therapy is now termed in contradistinction organotropic. This is extremely difficult to carry out without empiricism. Neither the drugs nor the tissues acted upon are constants and diseased tissues are often much more sensitive to drugs than are sound ones. Hence the necessity of individualization in organotropic therapeutics.

**Fifty Years of Gastroenteric Therapeutics.**—Ewald enumerates the many advances during this period—last but not least he mentions the modern sanatoria for digestive disorders in which dietetic therapy is carried out in perfection. The remarkable advances obtained through radiography are enumerated, while for the parallel progress in rectosigmoidoscopy credit is given to Americans like Tuttle, Otis, and Kelly, who substituted for the short rectal specula the much longer one now in use. The tremendous encroachments of surgery in the field of gastroenterology do not antagonize Ewald's belief that the latter is destined to become more and more a specialty. Martin, the American proctologist, receives credit for an intrarectal surgical advance, to wit, the division of Houston's valves. This has recently been revived in Germany. Of numerous drugs successfully introduced during recent years are biliary acids and the peristaltic hormone, and mention is made of the efforts to prevent intestinal putrefaction by artificial sour milk, Kefir, yoghurt, pot cheese, etc. It is, of course, understood that the entire routine technique of gastroenterology with its analyses of stomach contents and feces has come into use during the life of the *Wochenschrift*.

**Treatment of Incoercible Hemorrhages in Nurslings.**—Blühdorn refers to miscellaneous cases of bleeding dependent on hemophilia in some degree—melena neonatorum, Henoch's purpura, umbilical hemorrhage in sepsis, etc. The hemophilia does not imply the congenital type, but is a temporary, perhaps localized acute hemorrhagic diathesis. In the case of melena horse serum was injected and calcium (acetate) given *per os*. The child made a brilliant recovery. The horse serum used was ordinary diphtheria antitoxin. In the case of Henoch's purpura there was also hemorrhage from the bowels, which recovered under the same treatment. In the third case the umbilical blood was found to present delayed coagulability. The same treatment was given with great success. That it acts by restoring normal coagulability in the blood has not been proved nor is there necessarily a delayed coagulability in these cases.

### Münchener medizinische Wochenschrift.

*December* 31, 1912, *and January* 7, 1913.

**Serotherapy in Melena Neonatorum.**—Franz begins by mentioning the high mortality of this affection (50-80 per cent.). In addition to the few time-honored remedies in use, calcium, adrenalin and gelatine have been introduced but without any changes in the death rate. Serotherapy has been tested in other aspects of hemorrhage—for example hemorrhagic diathesis expressed as umbilical hemorrhage. Despite favorable results the method has not been extended to melena, which is of course not necessarily hemophilic but may be due to a great variety of factors. The author has recently begun to treat these cases by autoserotherapy, injecting umbilical blood serum subcutaneously. The five cases tested all recovered, and in four recovery was surprisingly prompt. No untoward affects of the serum were noted.

**Action of Digitalis on the Various Forms of Cardiac Disease.**—Schrenk sums up as follows: In 17 mitral insufficiencies with more or less compensation 15 reacted promptly, and two with defective compensation negatively. In 4 cases of pure mitral stenosis two did not react, one was a case of hepatic stagnation, the other of dilatation and pulmonary infarction. In 31 with combined mitral insufficiency and mitral stenosis all reacted but 2, and in one of these there was severe myocarditis. Of 9 cases of aortic insufficiency digitalis was negative in 2, in one of which there was dilatation. When negative results could not be associated with cardiac conditions they could be traced to severe general or pulmonary affections. In several cases of association of tricuspid and mitral lesions the result was not significant as there was as a rule dilatation of the right heart and stagnation of the liver. In 30 cases of associated aortic and mitral lesions the behavior under digitalis was very irregular, and there were at least nine negative results in which various complications were accused. Of 33 affections of the myocardium, chiefly chronic myocarditis, there were 5 negative results which included two cases of goitre heart. In five cases of pericarditis with exudation, in which hepatic stasis coexisted, there was no reaction of any value. Nearly all the 21 cases of cardiac insufficiency of chronic nephritis (no manifest arteriosclerosis) the reactions were marked. In 13 cases with arteriosclerosis the results were good in 7. Here as elsewhere the increase of diuresis was one of the evidences of a positive reaction. Total failure generally argued a poor state of the cardiac muscle.

**Care of the Teeth in the German Army.**—Müller advises that a dental station be established in every garrison hospital, with every provision for the extraction and filling of teeth. Every army corps should possess a technical station for the manufacture of false dentures. From one to three days should suffice for the preparation of the latter. Civil practitioners must direct the stations until a military corps of dentists can be introduced. The former must be paid by the army administration in accordance with the size of the garrison. The future corps of army dental surgeons must be recruited from the dentists of the Empire, who must serve a certain number of years actively, time being allowed for study. After their term of active volunteer service has been completed, they are placed on the dental reserve list.

**Spontaneous Recovery in Graves' Disease.**—Grober relates a case in great detail of a complete spontaneous cure of Graves' disease, much superior in type to the various

medicamentous and surgical recoveries which only produce a sort of arrest, leaving patients still invalids. At the same time nothing new is claimed, for similar instances have frequently been reported, save that the credit has been given without question to the treatment employed—which credit is as a rule a matter of dispute, for, as already stated, medical and surgical measures seem able in the vast majority of cases to exert very limited powers. All complete cures are then perhaps really spontaneously brought about. As Graves' disease shows periods of activity and of latency we must watch cases for 2 or 3 years before we can pronounce as to permanent results. It is of course very seldom that an occasion is offered to study a case of spontaneous recovery as is the case with any serious chronic disease. In 1906 a woman aged 28 was seen with recent acute Graves' disease. Within 7 or 8 months the full picture of the affection had developed. After a thorough examination the patient dropped out of sight and was not seen again for four years. When she reappeared it was without any evidences of Graves', but, instead, a picture suggesting incipient tuberculosis. Two years later she once more appeared with the same picture aggravated, but the most careful research could not locate bacilli. She had developed "drum-stick" fingers. The author assumed the existence of a type of chronic latent pulmonary tuberculosis with development of bronchiectasis. There was a faint persistence of a few Graves' symptoms, but these were doubtless pure residues. The view that this disease may sometimes be of paratuberculous origin is not new. Whatever the nature of the cure it seems assured that it could not have been due to treatment, for the patient denied having done anything toward cure during the entire six years.

**Results of Prison Sentences for Young Girls.**—Ruprecht, a jurist of Münich, well known as an authority on juvenile delinquency, shows by numerous examples that female juvenile offenders when released from prisons naturally choose between crime per se and vice. They naturally choose the latter because the penalties are lighter. Thus for example a country girl aged 13 whose home was broken up by death and desertion wandered to Münich and was shortly after dismissed on a charge of theft with a reprimand. Soon after she was mixed up in a case of attempted murder and arson and was sent up for three years. Upon her release she at once became a prostitute. Another girl, only 12 at the outset of her career, was repeatedly given short terms for larceny, after which she was given a three-year sentence with compulsory education. At the expiration of the term she began the life of a street walker. In cases of this type hatred of work undoubtedly enters as a factor, but the "result of punishment" seems to be the chief component. Since a young girl, perhaps a mere child, sentenced to a correctional institution as an habitual offender against property emerges as a fully developed woman and enters into prostitution—which she has learned all about from fellow convicts—something must be done as a substitute for these imprisonments. Enforced education does not solve the problem, for it does not neutralize the inborn dislike of steady employment; but it is infinitely preferable to merely punitive sentence, and judging from the results claimed in certain countries is at present our only hope.

---

## Deutsche medizinische Wochenschrift.

*January 2, 1913.*

**Rachitis.**—Ribbert introduces a new conception of this affection which is known to consist in the excessive formation of lime-poor bone, which interferes with endochondral ossification, the medullary spaces projecting into the defective cartilage. However, the attempts to connect rickets with a special anomaly of metabolism is unsuccessful as are attempts to make the affection amenable to specific diet. In the meantime two other factors have come to the front. Rickets has been produced in animals by bacterial infections, while ablation of the thymus also sets up a rachitic condition. Nothing can be done by feeding with lime, but when rickets undergoes recovery lime is quietly deposited in the lime-poor bones. The abnormal character and behavior of the cartilage cells are such as would be explained by the action of toxic substances, and bacterial rickets alone is sufficiently suggestive of a toxemic state. The author, however, sees no sure foundation for a thymic origin of rickets, its rôle being an incidental one only. The dependence of rickets on improper feeding of any sort is well known and the latter undoubtedly acts by lowering the resistance or by interfering with metabolism. The organism seems unable to store calcium, but the direct action of some sort of toxic substance on the cartilage cells, inducing the necrosis, represents, Ribbert holds, the most significant rationale of the disease.

**Significance of Choked Disks.**—Schieck states that the absolute significance of this phenomenon is as follows: the cerebrospinal fluid penetrates into the preformed perivascular lymph spaces of the axillary cord in the optic nerve along the central blood vessels so that there is set up the characteristic edema of the optic disk. The cause of this behavior of the fluid is increased intracranial tension resulting from meningitis, tumors, etc., as well as local disturbances in the orbit and optic nerve itself. Finally there is a type due to intrabulbar disturbances due to lowering of the intraocular tension following injuries to the eye and in external loss of blood (due to collapse of the blood vessels). The phenomenon of choked disk is becoming of ever-increasing interest to the ophthalmologist, neurologist, and surgeon. Trepanations for the prevention of blindness have become so frequent in recent years that the general practitioner can no longer escape responsibility in these cases and must make ophthalmoscopy to some extent a part of his routine work, since it is he, Schieck says, who is usually the first to see cases of this kind.

**Perirenal Hematoma Following Scarlatina.**—Hering names scarlet fever as one of the affections which cause acute hemorrhagic diathesis, so any sort of extravasation in any locality need occasion no surprise. When the extravasation is extensive marked pressure symptoms may result. A case cited is of interest because the boy when convalescing finely and with no symptoms of any kind pointing to the kidneys from first to last developed pain about the navel and in the left testicle. There had been a temperature rise. When first seen by the author the boy was looking very pale, temperature subfebrile, pulse 150, thready. There was an abdominal tumor, vomiting, and obstipation. Diagnosis was made of ileus with beginning peritonitis. Patient was rushed to hospital, stomach first washed out. The testicle, which had now become much swollen, was now exposed and found to be infiltrated with blood. The inguinal canal was normal, and strangulated hernia was thereby excluded. Median laparotomy now revealed the usual evidences of peritonitis, but no point of obstruction. The perirenal tumor was now discovered and trial puncture showed blood. A lumbar incision was made after the small exploratory abdominal incision had been closed, and the hematoma dealt with in the usual fashion. As evidences of peritonitis persisted this condition was treated by medical measures (electric light baths, physostigmin, etc.). Death resulted on the third day. The diagnosis was paralytic ileus consecutive to the ingravescent hemorrhage. This hemorrhage had not originated in the kidney, but somewhere in its vicinity.

## Insurance Medicine.

### SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

#### THE LIFE INSURANCE POLICY.

The policy is the consummation of a contract which stipulates the amount which the holder is to contribute to the common fund and defines his rights and privileges, and is executed after the statements by the applicant, the report from the examiner and the inspection report have been carefully considered by the company.

According to a distinct provision in the application blank, the policy does not become operative or binding until delivery to the applicant and acceptance by him during his continuance in good health and payment of the premium. This provision is manifestly a just and proper one. Many applicants postpone the payment of the premium until the period of time allowed has almost expired or, as happens in a large percentage of cases, change their minds and decide not to accept the policy. The time allowed for the delivery of the policy varies from thirty to sixty days from the date of the examination. The procrastinating or vacillating applicants, if they are also unscrupulous, have an ample opportunity, therefore, to become suddenly anxious to pay for and secure the policy in the event of any illness or accident occurring during the stated period. This scheme is not an uncommon one. The two following cases, remembered on account of the large amount involved, may be cited: In the first case the applicant was stricken with an acute attack of appendicitis about three weeks after the application and examination were made for a policy of a quarter of a million dollars. He had not tendered the premium and it was questionable if he would ever have done so. Nevertheless, his private secretary hurried to the company's office with the premium on the day of the operation and took the policy without mentioning the illness. Death occurred a few days later. The second case reveals double fraud, for the applicant had failed to acknowledge a history of previous chronic appendicitis and there were no apparent signs at the time of the examination. The payment of the premium was delayed for some reason, until an acute exacerbation of the appendicitis happened to occur, several weeks after the date of the examination, and the first news of the illness was presented to the company in the form of a death-claim. Both cases plunged the company into extended and costly litigations.

An exception to the clause referred to in the previous paragraph occurs in the event of the issuance of a "binding receipt" by the agent in exchange for the premium, according to the terms of which the policy will go into force as soon as the risk is accepted by the company, provided the premium is paid in cash and the applicant is in good health at the time. In such cases the company must pay the claim even if the applicant dies between the date of the binding receipt and the actual issuance of the policy. The chief object of a binding receipt is to relieve the mind of an applicant who is anxious to have the insurance in force at the earliest possible date.

Laws have been enacted in several states requiring the companies to attach a copy of the application, or any instrument referred to in the policy, to the policy as a part of the contract. These copies are usually furnished in the form of photographs of the original papers. The propriety and wisdom of this procedure are so evident that many companies are carrying it out voluntarily in states where there are no such requirements.

Before accepting the policy and paying the premium, the insured should invariably make it a point to read the terms in the document as well as the attached copy of the application and assure himself that the conditions and privileges appearing therein are satisfactory and that all the statements made by him are complete and accurate. This precaution is seldom observed and failure to do so will occasionally lead to misunderstanding and discontent later on. In order to avoid misunderstandings as far as possible, there has been a marked tendency in recent years to simplify the form of the policy and to use plain unmistakable terms in the place of the obscure and technical legal phrases formerly employed.

Restrictions have been removed, in some instances to the point of excessive liberality, and excessive liberality in regard to traveling in an unhealthy climate, military and naval risks, suicides, lapses, surrender values and the like involves a certain amount of cost. Freedom from such restrictions, while of advantage to those who benefit by it, must be made largely at the expense of the many other policyholders to whom it is of no use. Fortunately, the additional cost of these concessions is very small when divided among all the policyholders.

The term "incontestibility" implies that no objection will be made to the payment of the claim when it becomes due, provided all the premiums have been paid. Practically all policies now written become incontestible in one or two years after the date of issuance. With the perfected facilities for inspection, aided by the use of the telephone and telegraph and the extensive system of commercial credits, this period of time is now considered sufficiently long to afford ample opportunity to a company for verifying the statements of the applicant upon which the contract is based. If the company finds that the insured has been guilty of misrepresentation and that he will not return his policy when called upon to do so, equity proceedings may be instituted to compel its surrender.

---

**Under What Presuppositions Are Apoplectic Attacks to be Looked Upon as Due to Accident?**—Scheu states that, under the law, an occupational injury must occur within a specified interval. Insidious affections cannot be ascribed to occupation without a review of the case. There must be a demonstration of undue muscular exertion or external violence. Cerebral apoplexy occurs in those predisposed under the most varied conditions. It frequently supervenes while the victims are following their occupation in the absence both of undue exertion and violence; yet the tendency is invariably to accuse the occupation. When a stroke has occurred to a patient while at work the following data should first be obtained: Was the victim previously healthy and, if not, what is the history of his diseases; was he ever a soldier; if married, are his children healthy; had he been known as an alcoholic; what was the nature of his regular occupation; was the labor on the day of injury in any wise different from his regular duties; was the case recognized by the physician first summoned as an "accident."—*Zeitschrift für Versicherungsmedizin*, V. 9, 1912.

# Book Reviews.

Digestion and Metabolism. The Physiological and Pathological Chemistry of Nutrition. For Students and Physicians. By Alonzo Englebert Taylor, M.D., Rush Professor of Physiological Chemistry, University of Pennsylvania, Philadelphia. Price $3.75. Philadelphia and New York: Lea & Febiger, 1912.

There have been published in recent years a large number of books on biological chemistry, which are chiefly in German. There is also a valuable series of monographs on biochemistry published by the English school of chemists, in which are summarized certain phases of our knowledge, in convenient form. Graham Lusk, too, has published an important monograph on nutrition, treating the subject largely from the calorimetric aspect. But this volume covers a somewhat different field. An unusually successful attempt has been made to explain in fairly simple language the chemistry of digestion, absorption and breaking-down of food in the body. A preliminary portion is devoted to a survey of the foodstuffs and their general composition. Following this is a chapter on the theory of ferment action, and then a chapter on digestion. After this, the metabolism of each one of the foodstuffs is considered separately, that is, the metabolism of carbohydrates, fats and proteins. There is next an unusually clear discussion of that still puzzling field, the creatin-creatinin and purin break-down. Three final chapters on autointoxication, metabolism considered as a whole, and the production and regulation of body temperature, complete the volume. Although many useful diagrams are scattered through the text, there are no pictures of apparatus, and analytical procedures have been entirely eliminated, thus permitting within a moderate space a very full discussion of our present beliefs on metabolism. The press work on the book is excellent, and the only points warranting criticism are two: the exceedingly dogmatic style in which statements are made, and the elimination of all references to the names of those who have contributed to the subject. The author apologizes for the latter sin in his preface, saying that such references occupy a very large space and that their discussion necessitates the inclusion of much technical detail. While this is no doubt true, yet it means that the student who reads this book is unable to verify a single statement in it, unless he does a large amount of supplementary reading in some other text which does furnish references. If he has a command of German, he can use the admirable Handbuch der Biochemie edited by Oppenheimer and recently completed in five volumes, which is as much overburdened with references as this book is free from them. There is a danger, however, that the student will assume a somewhat more dogmatic attitude than he usually does about his information, and will think that because he has read one book he is fully informed on biological chemistry, and not realize the enormous gaps which still exist in our knowledge. Then, too, it is only right that the student of biological chemistry should become acquainted with the names of the great investigators who have done so much to build up the edifice of this branch of chemistry, and, what is more important still, he should in some way be referred to a few of the great original papers in order to learn at first hand the way in which biological chemistry has grown from the first great discovery, that of urea by Wöhler in 1828. The dogmatism of the author's statements, just referred to, are no disadvantage in so far as they represent his personal opinions, which are so often suppressed in books nowadays, and as they stimulate to further reading in order to verify his attitude may possibly prove of benefit; so that taken as a whole the book must be regarded as a credit to an investigator who has himself achieved important discoveries in biological chemistry.

Textbook of General and Special Pathology. For Students and Practitioners. By Henry T. Brooks, M.D. Formerly Professor of Pathology at the New York Post-Graduate Medical School and Hospital; Consulting Pathologist to Beth-Israel, New York City and New Rochelle, New York, Hospitals, etc. Illustrated with 525 half-tone and other text engravings (110 in colors), also 15 full-page plates in colors, containing 40 figures. Price $6.00. Philadelphia: F. A. Davis Company, 1912.

While originally planned as a translation of Langerhans' Outlines of Pathological Anatomy, the present work grew under the author's hands to such an extent that it developed into a new treatise and is now presented by him as an independent volume. The number of useful books on the subject is already very large but this newest addition to the list exhibits sufficient excellencies fully to justify its appearance. One of its most distinctive and valuable features, perhaps, is the success with which the author has sought to make it of service to the practitioner as well as the student by putting more emphasis than is usually done on the clinical aspects of pathological processes. In this way the problems of diagnosis are very fully considered and the value of the book as a work of reference is greatly increased. The illustrations are unusually numerous and by the use of a very thin but perfectly opaque paper the volume has been kept within bounds as to size and weight in spite of its 1,100 pages.

Outlines of Early Development. For Obstetric Students. By R. W. Johnstone, M.A., M.D., F.R.C.S.E., M.R.C.P.E., Assistant to the Professor of Midwifery, University of Edinburgh; Obstetric Physician to the New Town Dispensary; Extern Assistant Physician, Royal Maternity Hospital, Edinburgh, with a preface by Sir J. Halliday Croom, Profesor of Midwifery, University of Edinburgh. Price 1/6 net. Edinburgh: John Currie, 1911.

This little book is a valuable adjunct to the ordinary text book of obstetrics, as it explains the essentials of what is known in regard to the embedding of the human ovum. The illustrations help the student to learn the terminology used by embryologists in describing the ovum, trophoblast and decidua.

The Extra Pharmacopœia of Martindale and Westcott. Revised by W. Harrison Martindale, Ph. D., F.C.S., and W. Wynn Westcott, M. B. Loud, D.P.H., H. M.'s Coroner for North East London. Fifteenth Edition in Two Volumes. Price £1 1s. ($5). London: H. R. Lewie, 1912.

This the fifteenth edition of the well known pharmacopœia of Martindale and Westcott, is the first edition to be published in two volumes. This change has been rendered necessary by the growth of the subject matter during the past two years. By these means Volume I. has been kept down in size practically to that of the last edition and, according to the preface, contains everything the physician and pharmacist are likely to require for immediate reference on therapeutic matters, whilst the second volume acts as a supplement for further study. Volume I. of the present edition contains more matter than did the whole of the last edition and is an exceedingly satisfactory and up-to-date description of the chemical and therapeutic properties of those extra-pharmacopœial chemicals and drugs which have attracted particular attention in the medical and scientific world. The volume also contains a vaccine chapter, one on organotherapy, a chapter on sterilization as applied to pharmacy and a general "Posological Index" which includes some 12,000 headings referring to the two volumes. Volume II. embodies analytical and experimental work, as well as résumés of investigations by eminent authorities tending to elucidate the causes of many types of disease. Both volumes contain a really remarkable quantity of medical and pharmacological knowledge and supply a veritable mine of information. The second volume, for instance, among other things, has synthetic notes, a note on physiological standardization, a list of patent or proprietary medicines with their approximate composition, essays in relation to animal organotherapy, and so on. In its present form the extra pharmacopœia is an epitome of valuable knowledge, written in pithy style. It is warmly recommended to physicians as a very useful reference book.

Microbes and Toxins. By Dr. Etienne Burnet, of the Pasteur Institute of Paris, with a Preface by Elie Metchnikoff. Translated from the French by Dr. Charles Broquet and W. M. Scott, M.D. Price $2.00. New York and London: G. P. Putnam's Sons, 1912.

It was, of course, inevitable that sooner or later a volume on microorganisms would be included in the Bibliothèque de Philosophie Scientifique and it was almost as inevitable that the editor of that collection should apply to the Pasteur Institute for a man to write it. The outcome has been most happy. Dr. Burnet has compressed into a small volume a record of the results of all the most important of the innumerable labors which have accumulated on microbes and their toxins. Details can not be expected in a work of this extent and yet the reader will be surprised to find how numerous are the details which are discussed. It is naturally impossible to produce such a book without resort to technical language, yet the author has reduced this to a minimum and the fairly ample glossary should enable the layman to read understandingly. The translators have preserved the spirit of the original and the result is an attractive volume which should have great fascination for anyone interested in scientific investigations.

## Translation.

# THE NEWER OPINIONS CONCERNING DIABETES MELLITUS.[1]

By O. MINKOWSKI,

PROFESSOR OF MEDICINE, BRESLAU.

*Translated by* GRAHAM LUSK,

PROFESSOR OF PHYSIOLOGY, CORNELL MEDICAL COLLEGE, IN NEW YORK CITY.

The "newer opinions" have recently been published in this country by von Noorden under the title of "New Aspects of Diabetes." No better discussion of them can be offered than is presented in the paper of Professor Minkowski, who was formerly the pupil of Naunyn, v. Mering, and Schmiedeberg, and the doer of the classical researches upon the effect of pancreas extirpation in dogs. The translator would also state that work in his own laboratory by Ringer has shown that the action of adrenalin upon metabolism in glycosuria is to cause a discharge of sugar from the glycogen repositories of the body. Work in his laboratory has demonstrated that protein and many of its constituent amino acids are convertible into dextrose and that the argument of von Noorden that amino acids stimulate the production of sugar from fat is absolutely untenable.[2] The translator reiterates the belief expressed frequently in his writings that carbohydrate does not originate from fat of ordinary diet or body fat in the metabolism of the higher animals.

---

### Professor Minkowski's Address.

In presenting to you today some of the newer views concerning diabetes mellitus, I am fully aware that for this audience the practical standpoint of the physician will most arouse your interest. If, however, I deal with theoretical considerations, it is only because the therapy of the day, more than we are conscious of and more perhaps than is good for us, is determined by current theoretical conceptions. Although it must be the object of a rational therapy to base prescriptions on a clear idea of the character of the functional disturbance, yet there is a certain danger that the attention may become fixed upon each newly established fact so that a one-sided conception results. Theoretical ideas give us a viewpoint from which to survey our experiences in practice. Each change of viewpoint allows new phases to come to the front and retires those from our vision which formerly had seemed most important in our eyes. After this manner one can explain the movements of fashion in therapy, and the peculiar phenomenon that methods of treatment which have appeared to be thoroughly established have been forgotten, only to be rediscovered later.

The study of diseases of metabolism in general, and, especially laboratory work upon diabetes, has taught us so many new facts in recent years that the therapeutic standpoint which had been thought to be the true one has begun to be materially modified. What to many may pass as the newest standpoint is abandoned by others in favor of a still newer one.

It has recently come about that one of the best-known authors[3] on this subject has stated that opinions which have prevailed for two decades concerning the theory of diabetes can today no longer be maintained. However, the therapeutic consequences of these changed opinions have not yet reached their full force. This author, von Noorden, comes to the final conclusion that the old and tried out method of limiting carbohydrate ingestion may be well founded, even from the new viewpoint, although the interpretation is now different. However, even though opinion may remain that way for awhile, yet it takes no especial gift of prophecy to foretell that some day some one again will earn great fame for himself through the discovery that one may beneficially influence diabetes mellitus by reducing the intake of carbohydrate!

The new theoretical views on the subject of diabetes mellitus touch on the fundamental questions regarding the subject: (1) What is the cause of the overloading of the organism with sugar? and (2) In which organ does the seat of the disturbance which produces diabetes lie?

It is denied by no one at the present day that every case of diabetes is associated with a hyperglycemia, and that the glycosuria is due to this overloading of the blood with sugar. Whether a glycosuria may occur without hyperglycemia, and only as the result of a special permeability of the kidney for sugar—a "renal" glycosuria, of which Weiland[4] has offered some examples—is another question; for in such cases the underlying metabolic disturbances do not occur as they do in "diabetic" glycosuria.

Although up to within a short time we were accustomed to consider in the practice of medicine that the cause of diabetic hyperglycemia lay in the inability of the diabetic organism to utilize sugar in the normal manner, we now see that eminent clinicians, I mention only the schools of Kraus and von Noorden, have taken the view that the diabetic hyperglycemia does not arise from a disturbance in the power of the organism to destroy sugar, but rather to the overproduction of sugar; and that there exists an abnormally increased mobilization of sugar, whether from deposited glycogen or from some other substance, together with an increased production of sugar from other sources, from proteins and perhaps from fat.

I find it very much to be regretted that these opinions, which were formerly only held by such physiologists as were informed concerning experimental glycosuria of short duration and who had had no experience with human diabetes, have also been adopted by clinicians. I fear that the result will be the introduction of new misunderstandings and a greater chaos of opinion in the already difficult doctrine of diabetes mellitus.

In the first place, concentration of the attention upon the catchwords "disturbed utilization" or "increased formation" gives no proper idea of the differences between the two theories. One cannot deny that a temporary elimination of sugar may be brought about by an overflooding of the organism with sugar, as in certain cases of alimentary glycosuria or through a sudden outpouring of sugar from the glycogen repositories as in the case of *la piqure*, and as probably also takes place in adrenalin glycosuria. Furthermore, those who, like myself, consider that the disturbed utilization of sugar is the principal factor in the origin of diabetes, do not deny that the production of sugar may be increased in the organism. The body which is not able to oxidize sugar is in a condition of carbohydrate hunger, notwithstanding the fact that its fluids are overladen with sugar. The regulatory

mechanisms which normally coordinate sugar production with sugar requirement are consequently continually stimulated. If, therefore, it should be proved that the production of sugar is greater than normal, this does not prove that the increased sugar formation is the cause of the glycosuria. It could just as well be the result of the disturbed utilization of sugar. The question is this: Can it be proved that the diabetic organism has the power of the normal organism to utilize sugar—whether that sugar be ingested or be produced within the organism itself? The newer views maintain that this is the case. It seems to me that the proof has not been offered.

It is true that most diabetics can utilize certain quantities of carbohydrate, and such utilization may increase when increased quantities are given. But one must recollect that human diabetes depends upon the reduction and not the complete abolition of a function, and that the powers of even a diseased organ may be partially increased when increased demands are made upon them. However, it has been denied that a disturbed condition of sugar utilization exists in the most intense form of diabetes, such as that which follows the extirpation of the pancreas, and this doctrine has been upheld on the strength of observations concerning the behavior of the so-called "respiratory quotient." The observations, according to my opinion, may be otherwise interpreted.

The respiratory quotient is the ratio between the volume of $CO_2$ produced and $O_2$ absorbed, and gives us information concerning the materials oxidized in the normal organism. In the case of the oxidation of carbohydrate, $O_2$ is required solely for the purpose of converting C atoms into $CO_2$, and the respiratory quotient is 1. The quotient is lower in proportion to the quantity of protein and fat oxidized, substances which are less rich in oxygen than are the carbohydrates.

In diabetes mellitus remarkably low quotients have been found, especially in severe cases. It has also been shown that after giving carbohydrates the respiratory quotient does not rise to the same extent as in the normal individual. Heretofore this has been accepted as a proof that the utilization of sugar has been disturbed. But in recent times, under certain conditions, high respiratory quotients have been found, even in diabetes. Von Noorden lays great stress upon the experiments of Porges and Salomon, in which the portal veins of dogs were tied in order to eliminate the action of the liver from the organism. After this operation the respiratory quotient became 1, and the same thing happened in the animals if in addition they were made diabetic by extirpation of the pancreas. Von Noorden concludes from this that muscle oxidizes carbohydrate only, the power remaining unchanged in diabetes. Putting aside all other objections against the validity of this proof, such as the severity of the operation for example, one may object to these conclusions on the ground that the respiratory quotient is only interpretative of the normal processes of metabolism. If, for example, the formation of sugar is disturbed, as would take place after eliminating the liver as a factor, then those atom groups which were formerly converted into sugar might be directly oxidized, and would then exert the same influence upon the respiratory quotient as sugar itself. In the last analysis the respiratory quotient depends upon the relation in which C and H atoms stand with regard to the $O_2$ necessary for their oxidation, and not upon the constitution of the material oxidized. I will mention only that the oxidation of lactic acid, $C_3H_6O_3$, yields a respiratory quotient of 1.

The idea that the utilization of sugars is not disturbed in diabetes, must of itself present great difficulties to the clinician. It appears to me that a "quantitative mental error" is here involved. How is one to imagine a continuous glycosuria of the intensity found in human diabetes or even in experimental pancreas diabetes without any disturbance of sugar utilization, and occurring only as the result of an increased sugar production? In the last analysis it can only happen through a delay in the mobilization of sugar. For even in the normal organism deposited carbohydrates are sooner or later converted into sugar and oxidized as such. Even though it is possible to conceive that an overflooding of the organism with sugar and consequent glycosuria may be brought about through the discharge of accumulated glycogen stores, as in the case of *la piqure*, how can it be possible that after the exhaustion of these reserves and during starvation a prolonged and intense sugar elimination takes place as the result of the over-production of sugar when the sugar utilization is not at all disturbed?

I need scarcely say that the hypothesis of an undisturbed utilization of sugar is not in accord with the opinions of recent years concerning the origin of diabetic acidosis, opinions which are based upon the idea that the appearance of aceton, acetoacetic acid and β-oxybutyric acids is caused by an insufficient combustion of carbohydrate. If the new hypothesis be accepted then these opinions are in need of revision. For the present I can see no reasons compelling the adoption of an hypothesis which is *a priori* so improbable.

The reason why the idea of an increased sugar production has lately come so much into the foreground is because of observations which are concerned with the second of the questions under discussion, that is to say, with the question concerning the fundamental origin of the diabetic disturbance.

Only a little while ago it scarcely seemed disputable that one might indeed consider a definite locality as the seat of the diabetic condition. In these days, however, when one again speaks of "diatheses" and pays attention to the patient's "constitution," the question is asked, is there a specific locality to which the diabetic disturbance may be attributed? Is not the disease rather a "constitutional anomaly," a "disease of metabolism," instead of being a localized disease of an organ?

One might consider it a sign of the times that "diathesis" should appear on the program of a congress of internal medicine—times in which the mystic again rears its head and the metaphysical necessities of man are revealed in an increasing interest in religio-philosophical speculations. But it is more than that, and perhaps I may be permitted to express myself about it in a few words.

The term "general disturbance of metabolism" is nothing but an aid for the description of disturbances which have not as yet been localized. The more profoundly one understands the processes of metabolism the more firmly convinced must one become that, in the higher animals at least, the separate phases of the metabolic processes are sharply localized. That is to say, corresponding to

the morphological differentiation of the organs, there is also a sharp differentiation in metabolic function. We hardly know anything of the "general metabolism" of protoplasm. Therefore, it is only another expression of the indistinct idea of a "general anomaly of the constitution," when the character of "metabolism diseases" is defined by Ebstein as depending on "the lesser value of the protoplasma due to inheritance." The presence of undeniable inheritance is not the determinant of a "general affection." Each particular characteristic is inheritable, the form of the nose, the color of the hair, as also the weakness of a definite function of an organ.

Whenever a disturbance of a very definite order occurs, such as that in diabetes mellitus, there is every reason to seek for a localization of this disturbance. But one must not forget the following: "Localization" does not mean that the whole process is limited to the bounds of a single organ. No organ works for itself alone. It depends on processes taking place in other organs, and the products of its own activity influence the functions of other organs. These products may be ferments which promote decompositions in the blood or they may be hormones which regulate the activity of cells. Functional disturbances in a certain organ may, therefore, affect other portions of the body.

Furthermore, the specific metabolism processes are not merely localized in the macroscopical organs, but in the individual elemental tissues of which the organs are composed. Indeed the differentiation extends not only to the varieties of cells, but also to the nuclei, stroma, and granules of which they are made up, and very likely even beyond the power of the microscope to determine anatomical differences. It is not necessary that all the component parts of an organ be involved in a certain pathological state, and, furthermore, it is quite possible that the affection may be concerned with elements having the same functions but situated in different organs.

And, finally, the injuries may not be confined to damage to a single organ. They may, perhaps, especially influence a certain organ, but the diseased condition may also be the result of the most variable possible combination of local influences. Just as the resistance of these elements against pathological factors may depend upon the inherited condition of a certain organ or tissue, so also certain correlations between organs or systems of organs (of functional interrelation, or of common embryological origin), may determine the individually different and often inherited susceptibility toward disease—the "preparedness for disease" of Pfaundler. It is possible that in the search after details during the past years this correlation has not been sufficiently considered. The researches of recent times have concerned themselves with the correlated functions of different organs, and also with the relations of various diseased conditions and parts to each other. It is a matter for rejoicing, and also of hope that these efforts may result in an increase in medical information. But it should not be forgotten that a knowledge of the correlation of the organs can only be obtained when a knowledge of the behavior of the individual organs is at hand, and it would be very regrettable if we should content ourselves as others have done at other times with unclear impressions. "Diathesis" should not again be permitted to become a word to be used where comprehension fails!

It has ever and again been the endeavor to explain diabetes as due to the disturbance of a definite organ. The nervous system, the liver, and in recent times the pancreas, have been credited with being the seat of the disease. I will not today discuss the question as to the extent to which lesions of the pancreas are responsible for the condition of diabetes. I will only mention incidentally that Weichselbaum has recently described changes which occur in the pancreas in every case of diabetes, changes which, on account of imperfect methods, were overlooked by previous observers. One might ask if these changes were the cause or the result of the diabetes. However, it cannot be denied from the phenomena which follow extirpation of the pancreas that disturbances of the function of the pancreas can lead to diabetes. The only question is, what is the manner of action of this organ whose absence leads to diabetes?

It will today scarcely be disputed that this action of the pancreas depends upon an "internal secretion," which many believe to be formed in the islands of Langerhans. As regards the significance of the product formed, it was until lately generally believed that it played a definite rôle in the normal oxidation of sugar.

But recently it has been suggested that the rôle of the pancreas should be otherwise regarded. The action of various organs having internal secretions has been more exactly determined, and it has been found that many organs such as the thyroids, parathyroids, adrenals, and the glandular lobe of the hypophysis influence not only the metabolism of protein and fat, but also exert a special influence modifying the behavior of carbohydrate in the organism. It has been sought by manifold variations in experimental technique, especially through the combined removal of two organs, or by the injection of materials from other organs, to reveal the interrelations existing between them. The results of such experiments, which were carried on especially by Falta, Eppinger, and Rudinger, have led these authors to construct a complex system based upon the idea that the stimulation or inhibition of an organ may be determined by the activity of other organs. It is claimed that a mutual inhibitory effect exists between the so-called chromaffin system, the adrenals, and the pancreas, whereas reciprocal stimulation exists between the thyroid and the chromaffin system. These already complicated relations which are alleged to play an important part in the regulation of metabolism are rendered still more intricate because the functions of the organs are not only modified by the chemical substances circulating in the blood, but are also under the control of stimulating and inhibitory nerves which again are subject to the products of internal secretion acting sometimes to inhibit, sometimes to stimulate, sometimes on the sympathetic, sometimes on the autonomic system of the vagus nerve.

From these ideas the following conception has been evolved regarding carbohydrate oxidation and the origin of diabetes. The liver directly controls the metabolism of carbohydrate, for excess of carbohydrate is deposited there in the form of glycogen to be converted into sugar when sugar is required. There also, in case of necessity, sugar is produced from protein, and, as some think, also from fat. The activity of the liver is regulated on the one hand by the adrenals and on the other by the pancreas. Adrenalin, produced in the ad-

renals, accelerates sugar production, mobilizes sugar from the glycogen repositories and increases the sugar production from other materials. On account of this, adrenalin injections cause glycosuria and in Addison's disease the sugar content of the blood is diminished. The pancreas, on the contrary, inhibits the production of sugar in the liver. Injections of extracts of the pancreas prevent the occurrence of adrenalin glycosuria, extirpation of the pancreas removes the inhibition over sugar production, permits, unrestrained, the accelerating action of the adrenals upon the liver, and, therefore, leads to the most severe forms of diabetes. But the pancreas and adrenals do not function independently. The pancreas is controlled by the thyroid, which inhibits its action. Therefore, alimentary glycosuria takes place in hyperthyroidism, and an increased tolerance for sugar in myxedema. The thyroid may itself be influenced by the glandular part of the hypophysis, its activity being increased. Hence in agromegaly, when there is increased functional activity in the hypophysis, glycosuria may result. The parathyroids act upon the thyroids in the reverse manner. Besides this, the whole mechanism is under the control of the nervous system, which sometimes through the sympathetic, sometimes through the vagus, either promotes or inhibits the glycosuria. Bernard's puncture of the floor of the fourth ventricle, for example, causes, through sympathetic stimulation, increased functional activity of the suprarenals, and, therefore, glycosuria. And so forth and so on.

It appears from this that the cause of the production of diabetes and the controlling factors thereof include almost numberless possibilities, which may explain the many variations which present themselves clinically. The supporters of these doctrines do not deny that in far the greater number of the cases the dominant rôle is played by the pancreas. But they ascribe to this organ merely the importance of a brake, whose removal results in the unhindered activity of adrenalin.

It is not to be denied that in the collection of observations upon which this theory rests there are many important facts, and there is no doubt that the authors have known how to use these facts in a skillful way in the construction of their theory. In expressing my conviction that some day this theory will fall like a house of cards built high in the air, I wish to emphasize the fact that this opinion is in no way due to prejudice in favor of the sole dominion of the pancreas. I certainly will not deny that other organs may contribute to regulate carbohydrate metabolism and, therefore, may have an influence upon diabetes. I, myself, many years ago, employing methods similar to those used by the authors previously named, sought to determine the correlation between the different glands having internal secretions, and I reported these investigations at the Kongress für innere Medizin in 1896. I did not continue the experiments at the time, because the results obtained did not satisfy me. The newer experimentors have been more fortunate in this regard.

The whole complicated system of mutual stimulus and inhibition does not necessarily represent the correct interpretation of the observations, but only one of many possible alternatives. To my mind the complicated system is inherently improbable.

Without further proof, it ought not to be concluded that one organ acts upon another, just because the end result of the action of one organ may be increased or decreased by the co-activity of another organ. It is just as though one argued that since a fortune may be accumulated by increasing the income or by diminishing the expense account, therefore, an increased income must decrease expenses, and *vice versa!*

Without prejudice to the idea of the highly probable nervous and chemical correlations existing betwen the various organs, one may still consider that the influence upon the organism caused by a functioning organ or by a lesion of that organ, is much more probably due to the fact that each organ has a certain positive and, for itself, specific functional obligation. In this sense the adrenals may contribute directly or indirectly to the mobilization of sugar; the thyroids may cause only an increase in protein metabolism, although they may also act in other ways to increase sugar formation. As far as the pancreas is concerned, I would, both upon experimental and clinical grounds, attribute to it a pronounced influence upon the oxidation of carbohydrate in the organism. Simple reflection shows that even in the scheme involving this division of function, the effect of an overactivity of the adrenals or of the thyroid would intensify the symptoms caused by the exclusion of the pancreas.

Perhaps it may appear to this audience that as far as medical practice is concerned it is immaterial whether the cause of diabetic glycosuria may be pictured in one way or in another. But as first stated, there is danger that proved therapeutic principles may be overthrown. If we today treat diabetes by diminishing the carbohydrate intake, it is because we endeavor in that way not only to cause sugar to disappear from the urine, but also to spare from activity a disturbed function, and thereby cause its entire, or, at least, its partial recuperation. Von Noorden does, in fact, state that even under the new doctrines, the tried and tested method of limiting carbohydrate ingestion, the "sparing therapy," still holds, because, he says, sugar of all other substances stimulates to the greatest glycogen production, "acts as a whip to the involved organs." But, strictly considered, this is perhaps not quite logical. One might argue that if the utilization of sugar be not disturbed in diabetes then perhaps there ought to be some replenishment of the sugars lost to the organism so that its capacity for work should be maintained; and that the more carbohydrate given in the food the smaller would be the amount of sugar necessary to be built out of the valuable protein. In this way it could readily come about that dietary formulæ might be prescribed, as was formerly done, so that the more carbohydrate a diabetic excreted the more he should be given in his food.

The danger of turning the therapy in diabetes in this direction is the greater because at present, as a reaction against an overdone restriction of carbohydrate, there appears to be a current opinion which would allow carbohydrate a larger place in the diet of the diabetic, and this has even led to the introduction of "carbohydrate cures."

As you are aware, these "carbohydrate cures" originated from the recent discoveries concerning diabetic acidosis. As before mentioned, the appearance of acetone bodies has been found to coincide with a deficient oxidation of carbohydrate. It has been found that withdrawal of carbohydrate

from the diet of healthy persons causes the appearance of acetone bodies, and such withdrawal in severe diabetes causes an increase in the intensity of the acidosis. In those cases of diabetes in which a threateningly high acidosis appears it has become customary to administer carbohydrate, in spite of the danger involved. It has been assumed, as indeed is the case, that even in severe diabetes the organism has some power to oxidize carbohydrate. If the carbohydrate ingested be increased in amount the quantity of sugar oxidized in the body is increased, even though this is accompanied by an increase in the urinary sugar.

As a matter of fact it has been shown that in certain cases administration of carbohydrate can be of advantage to the diabetic. And, besides, it has been demonstrated that carbohydrates of various origins behave differently in the organism. Especially striking in this regard is the recently much discussed "oatmeal cure," first introduced by von Noorden, with which one may not only fight the danger of diabetic acidosis but also, to a striking degree, may increase the tolerance for carbohydrate.

From personal experience I can confirm the effectiveness of von Noorden's oatmeal cure in certain cases. Perhaps I formerly underrated its value. In certain diabetic individuals in whom coma was threatening or had already begun, I have received the impression that the prescription of an oatmeal cure acted for the moment as virtually life-rescuing. But this happens only in a few cases, and the results are not permanent.

It cannot now be stated upon what the action of the oatmeal cure depends. At the last Kongress für innere Medizin a long, drawn-out debate took place upon this subject, following a communication by Magnus-Levy. All the speakers with one exception were of the opinion that it depended upon a specific action of the oatmeal. Magnus-Levy, as the result of his investigations, came to the conclusion that the action was due to a particular property of the starch contained in the oatmeal. Others attributed the action to a special effect of extractives in oatmeal, to ferments which caused the destruction of sugar in the body, to substances acting like hormones which influenced the glands concerned with sugar metabolism, to an action on the kidney changing its permeability, to special fermentation processes in the intestine, with perhaps the production of substances which, like glutaric acid, have the power to influence the elimination of sugar and of acetone bodies, and to other similar ideas. That an action of a special kind is present here is indicated by the remarkable fact that, during the oatmeal cure, there is a very considerable water retention in the organsm with a noticeable increase in body weight, and not infrequently a tendency toward edema.

One of the most important influences connected with the action of the oatmeal cure, as indeed with all carbohydrate cures, is the reduction in the protein intake with which they are accompanied. I can only confirm the experience of others that it is better not to add protein to the diet, as was first recommended when the cure was introduced. It is desirable, in order to overcome the acidosis, to reduce the fat intake as much as possible.

I administer, five times daily, plates of soup, each containing 50 grams of oatmeal flakes and 10 grams of butter, with a little salt and nothing else. As a matter of course, such a diet should only be given for a few days (three or four). Immediately after that one had best, even in cases of severe acidosis, take the risk of administering a strictly carbohydrate free diet, especially if the patient has been treated for several days previous with a sufficient quantity of bicarbonate of soda.

The value of a restriction in the quantity of protein in the diet is not only because protein yields sugar in metabolism, but also because of the peculiar effect which protein administration has in increasing the total metabolism. Although, generally speaking, the energy requirement of the organism is only slightly affected by the ingestion of food, yet protein has the power to increase the metabolism when it is administered in increasing amounts. A large administration of protein may, therefore, exercise an evil influence upon the progress of the disease by instituting increased demands upon the damaged function of metabolism. This is quite apart from the fact that protein leads to an increased acid production, and hence it must be considered an acid food which may increase the dangers of acidosis. In the many cases in which the power to oxidize certain quantities of carbohydrate is still intact, it is desirable to introduce this amount of carbohydrate in the food and to reduce the protein intake.

Perhaps the greatest value of the carbohydrate cures lies especially in the fact that through them the importance of reducing the quantity of protein in the diet has become known to a large number of physicians. Such procedure, however, is not entirely new. I need only recall that Naunyn, who above all others was most largely responsible for the introduction of a rational dietetic treatment of diabetes, always maintained that the regulation of the protein intake was of no less importance than that of carbohydrate; and, furthermore, the extensive investigations of one of his pupils, Weintraud, demonstrated the necessity as well as the actual possibility of reducing the total metabolism by this treatment.

Of course, a reduction in the total intake which involves diminishing the carbohydrate and protein intake simultaneously, especially at a time when much fat must not be given on account of the acidosis, presupposes that the amount of mechanical work accomplished by a diabetic so nourished shall be kept within restricted limits. Here one touches a not unimportant point in the therapy of diabetes; for since the utilization of sugar accompanies muscular work, it has been rightly maintained, that in addition to regulation of the diet, value also inheres in the taking of muscular exercise. And, as a matter of fact, in many cases of this disease increased muscle work reduces the output of sugar. However, when the power of oxidizing sugars has very largely been lost, then an increase of mechanical work does not increase the capacity to utilize sugar, but may even cause an increased output of sugar. In these latter cases the therapy indicated is to avoid, as far as possible, all excess in muscular movements.

These regulations concerning carbohydrate cures, reduction in the quantity of food and of protein taken and diminution of the muscular effort, concern only certain cases of diabetes and especially those of the severest type, with accompanying acidosis. In the great majority of cases the most desirable treatment consists first, in a reduction of the carbohydrate intake; second, in a compensatory increase in the fat ration; third, in a moderate increase in the protein taken, and fourth, in a regulated amount of muscle work. Strict dietaries should

be absolutely enforced in all mild cases of diabetes, because they are then fraught with little danger to the organism. On the other hand, benefit from the treatment is readily attained, there being not only a reduction in the sugar excretion, but even a recovery from diabetes or at least a very considerable augmentation in the tolerance for sugar.

It will ever remain an art acquired by special study of the condition of each case, how to obtain the best result, and how to accommodate treatment to the individual.

In conclusion, permit me one remark. An author[5] who has been recently especially prominent in recommending carbohydrate cures in diabetes feels that there is a special advantage in them, as contrasted with dietaries containing the flesh of animals, in that they are "humane." Here, be it noted, that the diet poor in carbohydrate is not exclusively "animal" in nature but, on the contrary, greatest value will always be attached to a liberal use of vegetable food in the form of those permissible vegetables which are poor in carbohydrate, in the form of salads and of certain fruits. One should term "humane" that diet with which one can best relieve the patient.

### NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

*Stated Meeting, Held, December 26, 1912.*

Dr. Franklin A. Dorman in the Chair.

**Multiple Fibroma with Adenocarcinoma of the Fundus Uteri.**—Dr. W. Travis Gibb reported this case. He said that the patient was 50 years of age, married, and the mother of one child. She had always had more or less uterine disturbance and the menstrual function had always been irregular. She had been confined to her bed for weeks at a time from April to October, 1911. The attending physician had never made an attempt to ascertain the cause of the hemorrhage and the treatment had consisted in the internal administration of ergot and stipticin. When the patient first presented herself to Dr. Gibb she had been flowing continuously for several months. The uterus reached several inches above the symphysis and was the seat of several subserous and intramural fibroids. There was also a large polypoid mass in the interior of the uterus which bled very easily. As the uterus was too large to be removed through the vagina and the condition of the patient made it seem unwise to risk a suprapubic hysterectomy at that time, the uterus was emptied of the polypoid growth, which was about the size of an orange and was attached to the fundus near the right cornu. The microscopical examination of this growth showed it to be an adenocarcinoma. The patient made a quick recovery and the uterus reduced in size so rapidly that a vaginal hysterectomy was performed a week later. The microscopical examination of the tissues surrounding the attachment of the carcinomatous mass indicated that the cancerous infiltration had not extended through the uterine wall. The patient made an uneventful recovery from the second operation. This case was of special interest because it illustrated what was occurring every day. The patient would have been willing to undergo any operation or to do anything that held out hope of relief, but her physician allowed her to go on for two years without making any real effort to ascertain the cause of her condition. Thus two very valuable years were lost in her treatment. Fortunately for the patient in this instance the cancer was one of slow growth and very amenable to surgical treatment. Two years ago the patient might safely have been promised that she would have no recurrence but at the present time the danger of recurrence in the pelvis or by metastasis was very great. Malignant disease of the uterus complicating uterine fibroid was of much more frequent occurrence than was generally believed a quarter of a centry ago. At that time the idea was prevalent that the presence of uterine fibroids was proof that cancer was not present and would not develop in the uterus. The belief now prevailed that malignancy accompanied uterine fibrosis so frequently that they were justified in removing all fibromyamatous uteri, especially in women over 40 years of age. Malignancy in connection with uterine fibroids occurred in about 5 per cent. of women between 40 and 50 years of age; in about 12 per cent. of those between 50 and 60 years of age; and in about 23 per cent. of those between 60 and 70 years of age. Such statistics should lead one to choose a panhysterectomy in those cases rather than the easier supravaginal operation, not only because a minute cervical fibroid might exist unnoticed at the time of the operation and develop later on, but because there was danger of the development of malignant disease in the cervical stump if that were not removed.

**Double Pyosalpinx of Large Size.**—Dr. W. Travis Gibb reported this case which occurred in a woman 34 years of age, married, but never pregnant. He stated that she had been ill practically since her marriage, had been curetted twice, had worn pessaries, and had undergone many courses of treatment. Both she and her husband denied any venereal disease. She had recently been ill for several weeks and confined to bed for several days with a sharp attack of peritonitis. Examination showed the abdomen enlarged, tense, and with a well-marked mass in the right iliac fossa. This mass extended 4 or 5 inches above Poupart's ligament and well over toward the median line; it was rounded, exquisitely tender, and appeared to be directly continuous with a fluctuating mass filling the cul-de-sac. A diagnosis of pelvic abscess was made and preparations for its removal through the vagina were in progress, when examination under complete anesthesia showed the mass in the right iliac region to be distinctly separate from the mass in the cul-de-sac and fairly movable in the abdominal cavity. An abdominal operation was then undertaken. Through a median incision a large mass presented, covered with thickened and inflamed omentum. The latter was adherent to the parietal peritoneum. The mass was firmly adherent and all the pelvic and lower abdominal contents were firmly matted together by old adhesions. In attempting to enucleate the upper mass pus escaped freely, perforation having occurred at several places. When the mass was separated and lifted out it was found to be the right Fallopian tube and an enormously enlarged ovary. The tube was over 12 inches long and 3½ inches in diameter at its fimbriated extremity. The ovary was about 4 inches long. Before removal the tube reached to a considerable distance above the umbilicus. The omentum was so adherent to the tube that portions of it had to be ligated and removed with the tube. Several knuckles of intestine were so firmly adherent to the tube that undoubtedly the tube had ruptured into the intestine during previous attacks. Efforts to separate the adhesions resulted in several tears in the intestines, which necessitated extensive repairs. The left tube and ovary were firmly imbedded and adherent in Douglas cul-de-sac. They, too, were enormously enlarged and were removed with difficulty. This woman no doubt had had many attacks of pelvic and general peritonitis due to gonorrheal tubal infection, some of them terminating in tubal abscess which ruptured into the intestine. It was difficult to see how the tubes and ovaries were permitted to grow to such enormous size without operative interference.

Dr. Franklin A. Dorman said that from Dr. Gibb's description the tumor was larger than any he had encountered of similar character. In this case pus pockets had formed and the tumor measured 12 inches long and was 3 inches in diameter. There was one large cavity.

Dr. George Gray Ward said that from the description it must have been a very large tumor and that he had never seen one as large.

**Interstitial Pregnancy; Ruptured.**—Dr. George Gray Ward, Jr., reported this case and presented the specimen. He stated that the patient was twenty-seven years of age and had been married five years. She gave a history of having become pregnant soon after marriage and of having had an abortion produced by midwife. This was followed five days later by peritonitis which nearly cost her her

life. She had had no further pregnancy until about four months ago, the date of the last menstruation being August 4, 1912. This gestation progressed normally until the evening of November 28, when, after laughing heartily at the theater, she felt a severe sharp pain in the region of the uterus which lasted about five minutes. She felt nothing more until the following morning when she was seized with a severe pain in the same region as the night before, but much more severe. Her family physician was called and recognizing the seriousness of her condition ordered her removal to the hospital. The ambulance nearly collided with a trolley car and this sudden jar caused the woman to go into collapse, and undoubtedly at this time the fetus was expelled into the abdominal cavity. On reaching the Post-Graduate Hospital she was taken immediately to the operating room, and given an intravenous saline infusion and prepared for operation. The abdomen was found filled with fresh blood and clots, and a four months' fetus was found lying loose among the intestines. The uterus showed a large rupture at the right cornu. A rapid supravaginal hysterectomy was done, and the abdomen cleansed and closed. The entire time consumed in the operation was thirty minutes. The condition of the patient was precarious for twenty-four hours, the pulse being imperceptible at times. Rectal saline enemata and Murphy's drip were employed. She then recovered rapidly and was up on the fourteenth day. The specimen showed very clearly the development in the right horn of the uterus and the intact tube beyond. Dr. Ward said he reported this case because these cases of interstitial pregnancy were of sufficient rarity to be reported. According to Rosenthal the interstitial variety was the rarest, occurring in only 30 per cent. of the 1,324 cases of ectopic pregnancy. Weinbreuner collected only thirty-five cases up to 1904 and Martin and Orthmann found only one instance of interstitial pregnancy in fifty-seven ectopic pregnancies. Among the special points of interest in this case were the following :(1) Points bearing on the etiological factors. After she was married and became pregnant she attempted to rid herself of her pregnancy and this probably was an etiological factor in the production of the ectopic gestation. (2) She had no symptoms during her four months' pregnancy that would lead one to suppose there was a pregnancy other than in the uterus. There was no spotting and no pain. The uterus was enlarged to what would be expected when there was a four months' pregnancy *in utero*. He could not say how they were going to guard against such calamities. (3) The question arose, why did he remove the uterus? Dr. Ward thought this was a fair question. At the time of operation the woman was so nearly dead, pulseless, abdomen filled with blood, and in shock and everything had to be done with great rapidity and there was no time to be lost and, therefore, he got it out as soon as possible. He believed he was able to do a quicker operation by doing a supravaginal amputation and so removing the bleeding areas. When one realized that the ectopic was in the horn of the uterus he should remember that the hemorrhage came not only from the ovarian vessels but from the uterine vessels as well. Therefore, to make sure of stopping the bleeding, and that in the quickest time, he removed the organ. The patient made a good recovery.

Dr. Franklin A. Dorman asked Dr. Ward if an expert had examined a woman with such an ectopic before rupture, whether he could have obtained any hint as to the true condition by discovering some irregularity. In Dr. Ward's judgment, would the discovery of any such irregularity suggest the existence of such a condition? Dr. Dorman remembered one case in the service of Dr. West seen at the Post-Graduate. There were tremendous explosions of this sort in an undeveloped horn. The operation verified the diagnosis and it was similar to Dr. Ward's case.

Dr. Ward said that it would seem to him that in an examination made by an expert, it was possible if the case was examined carefully and the abdominal walls were not too thick to detect any irregularity which might exist. In this instance the ectopic was in the horn of the uterus. Careful bimanual examinations were not always made. He believed that it was excusable not to recognize the condition under the circumstances. In some instances, however, a careful examination would reveal irregularity. Dr. Ward remembered one other case of interstitial pregnancy which was reported before the New York Obstetrical Society by Dr. Vineberg a year or two ago. The top of the uterus appeared as if it had been blown off by a shotgun. In ordinary tubal pregnancy such severe hemorrhage with collapse was met with commonly and often one waited until the following morning to operate, but in the interstitial variety the hemorrhage was apt to be of the most severe type.

Dr. Franklin A. Dorman showed a picture of a case of Dr. Marcoe's that was reported to the Section last winter. In this case there were preliminary symptoms of bleeding and no rupture.

Dr. William H. Wellington Knipe said he would like to believe that they could make a diagnosis of these cases by the discovery of these irregularities of contour. The textbooks stated that a pregnant uterus should be smooth and round, but they frequently met with uteri which were neither smooth nor round. During the early months he was quite sure he would hesitate in making a diagnosis of pregnancy of the type under consideration just because of a little irregularity of the uterus. He saw many cases with irregularities in normal pregnancies. He did not believe that they could make a positive diagnosis merely by an abdominal examination. One might have a symptomless patient; an abdominal as well as a vaginal examination might be made and if such a diagnosis of intramural ectopic was made he believed it was guesswork. These irregularities of contour, in his opinion, were not so important in establishing a diagnosis as some thought them to be.

**Sarcomatous Degeneration of a Uterine Fibroid.**—Dr. L. J. Ladinski reported this case, which occurred in a woman forty-six years of age and married. Her family history was negative and her health had always been good until during the last four years when she had lost in both weight and strength. Her last menstrual period was five weeks before her admission to the hospital. She had been married twenty-five years, had seven children, and no miscarriages. Her first pregnancy was twenty-three years ago and her last eight years ago. During the past four years menstruation had been regular, but very painful, profuse, and lasting from eight to ten days. She had not menstruated for ten weeks and then flowed profusely for five weeks before her admission to the hospital. She had continued to bleed until a week before her admission. Urination was normal; the urine, however, showed a trace of albumin. The patient also complained of headaches. A vaginal hysterectomy was done at the Beth Israel Hospital and the report of the pathologist showed sarcomatous degeneration of the uterus.

**Adenosarcoma of the Cervix Following Supravaginal Hysterectomy for Fibroids.**—Dr. L. J. Ladinski reported this case. He stated that the woman was forty-five years of age, had been married twenty-four years, had had no children, and no miscarriages. She had menstruated regularly until February, 1910, when a supravaginal hysterectomy was performed for fibroids of the uterus. She was referred to Dr. Ladinski in September, 1910, because of severe pain and difficulty in urination and defecation. Upon examination a large mass the size of an orange was found occupying the place of the uterus and extending principally to the right. Assuming that the tumor was a fibroid and had developed from a small one overlooked in the cervix at the time of the operation, the case was diagnosed as one of fibroid. Upon opening the abdomen a mass was found adherent to the omentum and appearing to spring from the stump of the cervix. It was somewhat adherent to both rectum and bladder. After removal of the tumor and cervix the patient made an uneventful recovery. The report of the pathologist stated that the tumor had an irregular nodular surface, was brownish-yellow in color, rather firm in consistency, and had fatty bands like portions of the omentum firmly attached to the greater part of its surface. Grossly the tumor resembled a degenerated sloughy fibroid. On cross-section the surface was yellowish and irregularly lamellated. The frozen section showed a papillary adenocarcinoma. This was confirmed by section of the hardened specimen. There were signs of very active proliferation. The carcinoma had invaded some of the attached omental adhesions. The smaller tumor was irregular, of firmer consistency, and showed on microscopical examination that the cervical glands were retained. The patient had gained 20 pounds since the operation and was in splendid physical condition. This case was interesting because of the coexistence of fibroid and carcinoma and the question of the possible causative relation between the two conditions.

**Malignant Degeneration Association with Fibroma Uteri.**—A general discussion was called for.

Dr. Franklin A. Dorman asked what was believed to be the attitude of the gynecologist towards a woman with fibroids of the uterus and whether the uterus should be entirely extirpated. Until recent years few recognized the considerable possibility of malignancy occurring in these tumors. During the early days of his practice it was thought best to wait until the menopause before interfering, especially in the cases with menorrhagia.

Dr. George Gray Ward, Jr., said that this subject was interesting to all operators who wanted to know whether or not it was best to leave the cervix. During the past two years there was a strong leaning abroad toward curing these fibroids by *x*-ray treatment. In some of the clinics *x*-ray was relied on almost exclusively except for those women who did not have the time or the means to take the *x*-ray treatment. The theory was that the *x*-ray caused the ovaries to cease functionating, the myoma to shrink, the blood vessels to atrophy, and the symptomatology to disappear. Dr. Ward said that he had questioned the men who were using the *x*-ray treatment in regard to the danger of malignant degeneration, and they admitted that 10 per cent. of the fibroids showed degenerative changes of a malignant nature. If one out of ten showed these changes they should seriously consider whether it was worth while to use this expensive *x*-ray treatment. More care should be exercised in ascertaining whether a growth was malignant; one should not jump at a conclusion at the time of operation without cutting open the growth. It was one's duty to open these tumors in the operating room.

Dr. William H. Wellington Knipe recalled a case seen some years ago in which a supravaginal hysterectomy was done for a large fibroid. About four months later he was called to see this patient and found a mass so hard that he thought he had to deal with a fecal impaction. He finally made a diagnosis of malignant disease of the rectum and sigmoid. At the time of the hysterectomy they did not suspect this condition; the broad ligament was filled with large vericose veins. In such cases the best plan was to consider the condition a malignant one and to do an extensive operation. In regard to the degeneration of fibroids into cancers, he recalled a case in which he suspected that this might have occurred and consulted Dr. Prudden, who made the statement: "These never degenerate into cancers." Dr. Knipe's opinion leaned to that of Dr. Prudden. In case of malignancy the cause might not be independent of the presence of fibroid, but might be due to irritation set up by the fibroid. He had never seen nor read of a case in which a fibroid nodule had been converted into a malignant tumor *per se*.

Dr. M. Rabinovitz said his experience had taught him that less than one in ten fibroids degenerated into malignancy and therefore it was impossible to lay down any fixed rules as to when to do a myomectomy and when a hysterectomy. He thought the age of the patient and her social position should be taken into consideration. If the woman was in the prime of life and desired more children or was a nullipara whose sterility might be due to the presence of fibroids the proper procedure was a myomectomy. In women approaching the fourth decade who could not be kept under observation hysterectomy was preferable. As to the question of the degeneration of fibroids, he had observed that the degeneration was limited to the tumor and only exceptionally did it extend to the uterus. Furthermore, the microscopical evidence was not always borne out clinically. He related two instances in which the pathologist's report on the scrapings was that of adenocarcinoma in which the patients had refused operation and no malignancy developed. The second patient died of an intercurrent disease and sections of the uterus showed no carcinomatous changes except in the curettings.

Dr. Franklin A. Dorman said that one of his colleagues had told him that he had met with two or three recurrences in the cervical stump. As a result that man employed retention of the stump and excision of the cervical mucosa. They should safeguard their patients and often a panhysterectomy was the operation to be preferred. If, as reported, 10 per cent. of these became malignant, this operation, he believed, gave them a better chance.

Dr. W. Travis Gibb said there had been a great deal of talk about adenocarcinoma of the fundus. This was a slow growth. Eighteen years ago he operated upon a patient who was about fifty-five years old. The curette went through into the abdominal cavity and he felt called upon to remove the uterus. It was his privilege to again see her eighteen years after the operation. In those cases where the fundus was involved he believed the cervix should be removed because it might become the focus for further development. Even when the fibroids were very small this should be the course to pursue. All had seen cases in which these small fibroids had been overlooked and, for that reason, he believed a panhysterectomy was the best operation. The proportion of cases that developed malignancy he believed to be very large. Greater care should be taken in making the diagnosis; many of the cases seen in the past were carcinomatous at the time of operation.

**Election of Officers.**—*Chairman*, Dr. George Gray Ward, Jr. *Secretary*, Dr. George W. Kosmak.

## SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

*Twenty-fifth Annual Meeting, Held at Old Point Comfort, Virginia, December 17, 18 and 19, 1912.*

The President, Dr. J. M. T. Finney, of Baltimore, in the Chair.

(*Continued from page 179.*)

**Proctoclysis; Experimental Study.**—Dr. Hugh Trout of Roanoke, Va., said in February, 1912, he presented a preliminary report of a comparative study of normal saline solution and tap water for proctoclysis in nearly one thousand cases. The present report was based on over two thousand cases and included all types of operations as well as replies received, from two hundred and thirty-two hospitals with the following deductions: "(1) There is no uniformity in preparing saline solutions in the various hospitals. (2) A soft rubber catheter is employed instead of a hard nozzle, and very seldom does the patient realize anything is in the rectum. (3) All sodium salts are toxic and quite frequently dangerous doses are being given by the rectum. (4) Tap water does not iritate the rectum, and patients will absorb one-third more than they will of salt solution. (5) It requires twice as much water by mouth to relieve thirst when patients are taking salt solution by rectum. (6) Salt solution does not seem to have any effect on the renal functional test of phenolsulphonephthalein. (7) Twenty-seven cases have tasted salt without knowing the character of the solution they were taking by rectum. (8) Fifty-eight cases have been operated on at other hospitals, and all have commented on the absence of thirst and decrease in nausea in comparison with previous operations. (9) Two hundred and eighty-seven operations on the perineum and rectum in which proctoclysis could not be employed, have been in the hospital during this period, and all showed a marked increase in thirst and nausea in comparison with other cases. (10) Four cases of death reported in the literature from the use of salt solution. (11) The giving of fluid by rectum meets nature's demands for the relief of postoperativ thirst in a simple, effective, and harmless manner."

Dr. J. Wesley Bovée of Washington, D. C., congratulated Dr. Trout on his work in this direction, because it was painstaking and thorough. He had no idea he would get nearly as good results with plain or tap water as with water containing salt, and he said this after having had a large experience in the use of salt solution.

Dr. Ernst Jonas of St. Louis, Mo., said they had been changing from saline solution in the rectum to plain water proctoclysis, and although he could not give the exact statistics he could confirm the very favorable report of the essayist. Patients had been much more comfortable. Edema of the legs had been observed less frequently.

Dr. F. W. McRae of Atlanta, Ga., said in one case he knew of a stronger salt solution was used instead of the usual dilute salt solution, and death supervened twelve hours later. It was a simple appendectomy where the nurse used a pint of the stronger solution.

Dr. F. W. Parham of New Orleans said that for some time he had been using very much weaker solution, namely, one-tenth of 1 per cent. solution, in place of the ordinary normal salt solution, but had not done it as systematically as the essayist, who had brought out clearly the advantages of using water in place of salt solution in most of these cases.

Dr. J. M. T. Finney of Baltimore had had the opportunity of seeing some of Dr. Trout's work and knew the care with which these observations had been made and the long series of cases which they covered make it a paper of great importance in view of his findings.

Dr. Robert Milne of London, England, said it would be interesting to know the temperature of the top water in the receptacle. At the London Hospital they gave salt solution as a routine for years, and in the receptacle the temperature of it was 105° until some one found that when the saline solution came out of the end of the catheter its temperature was only about 90°, that is, in running through a rubber tube three or four feet long the saline solution drops about fifteen or twenty degrees in temperature. Since then they usually kept it in a thermo-flask at the foot of the bed and kept it in that flask at a temperature of 120°.

Dr. O. H. Elbrecht of St. Louis, Mo., said if one would take a tube six feet long, which was about the average length of the tube which would he used for proctocylsis work, he would find there was a drop of 40° in tempera-

ture in the six feet of rubber tubing, with the water running at the rate of 60 drops per minute. This he simply used as a standard to gauge how much salt solution would run in in an hour.

Dr. W. P. Carr of Washington, D. C., had always been rather afraid of salt solution, especially used intravenously and subcutaneously, and he did not think he had given it intravenously in half a dozen cases, and he seldom used it under the skin. He was glad to hear of such gratifying results from the use of plain tap water.

Dr. Trout, in closing, said he had been able, except in a few cases, to get nine quarts of salt solution in the rectum. He had found drainage cases absorbed more than any other class of cases. He used 3,500 to 4,000 c.c. in the water cases, and with salt solution he used from 2,500 to 3,000 c.c. He gave it every two or three hours by catheter, would let it run in, and then take out the catheter.

**Acute Invagination of the Ileum Secondary to Sarcoma of the Small Intestine.**—Dr. C. Jeff Miller of New Orleans reported a case and said a search through the list of reported cases revealed only a few similar instances in which sudden acute symptoms gave the first warning of intestinal trouble. He found only three such cases in Moynihan's list. In the other thirty-seven cases symptoms of transitory abdominal pain, occasional vomiting attacks, and nausea preceded the recognition of the growth from a few weeks to over three years. If there could be a cardinal symptom it would be the presence of a tumor. It was present in over 90 per cent. of the cases when brought for examination or operation. It was always present in children and nearly as constant in adults. More than half the cases were reported in patients over forty years of age. Cachexia was only marked in children, except in the late stages. Fever was often present, as might be expected from the large percentage in which ulceration occurred. Constipation was not a reliable symptom, although often present. Diarrhea was noted in a few. Three cases had been reported as occurring in the ileum years after severe attacks of typhoid fever, and Nothnagel reports an instance of sarcoma that developed from tuberculous ulcerative scars. In thirty out of forty-six instances the growth was single, in sixteen multiple. It was curious to note the frequency of adhesions between the bladder and involved coil of intestine. In forty-six cases Lecene reports adhesions in twelve, seven of which were instances in which the bladder was the involved structure.

**Extrauterine Pregnancy.**—Dr. Stuart McGuire of Richmond, Va., reported five cases on which he had operated a second time for extrauterine pregnancy. He quoted Dr. Richard R. Smith, who tabulated 2,998 operations for tubal pregnancy, in which recurrence followed in 113 cases, or 3.8 per cent. He did not believe these figures represented the true frequency of the accident, as he thought it was impossible to follow up such cases accurately over a sufficient period of time to get final results. While he agreed theoretically with the rules laid down by Smith, he did not think they would prove of much service practically, as they left the decision of the question too much to the patient. A woman just before an operation for ruptured ectopic pregnancy was in no condition to understand or settle a complicated proposition. If she decided either for or against the removal of both tubes, she would in after life frequently regret the responsibility of the decision, fearing on the one hand a repetition of her former accident, or indulging on the other in morbid longings for a child whose advent she had made impossible. The operator should settle the question for himself, without taking the woman into his confidence, remembering all the time that a surgeon's and a patient's attitude to an operation was often very different, and that their estimate of the desirability of a baby was often very far apart. In deciding the question the surgeon should try to put the patient in the position of a member of his own family and ask himself, "what would I want done if this were my wife, or my sister, or my daughter?"

**The Indications for Abdominal Cesarean Section.**—Dr. Reuben Peterson of Ann Arbor said the more common indications for this operation were obstructions to labor, pelvic contractions, fibromyomata, ovarian tumors, stenosis of the cervix and vagina, and miscellaneous, such as previous ventrofixations, and large size of the child. Other indications were uterine hemorrhages, concealed accidental hemorrhage, placenta previa, constitutional crises, eclampsia, and contracted pelvis. Probably more cesarean sections would be performed for this indication than for any other. The operation was imperatively demanded in cases where the conjugata vera measured 7.5 centimeters or less and the child living. When the child was dead and the true conjugate was 6.2 centimeters or under, cesarean section was still indicated, on account of the danger to the mother of attempts to deliver the craniotomized child through such a small pelvic diameter. He was at present engaged in tabulating the results of 425 cases of eclampsia treated by abdominal cesarean section, and some very interesting facts were being brought out. Not only had the literature been carefully searched and all recorded cases been collected, but many operators all over the world had been kind enough to furnish him with unpublished cases. Thus the statistics represented not the work of a few, but over 200 operators. The total maternal mortality, counting patients operated upon before the aseptic era, was 36.9 per cent., while this was reduced to 31.8 per cent. if only the 317 patients operated upon since 1900 were counted. The 50 per cent. mortality ascribed to abdominal cesarean section in the treatment of eclampsia could be explained by errors in the selection of cases, for many eclamptic patients were subjected to the operation who were hopelessly septic. These patients did not die from the eclampsia or the operation itself. Many of them perished because of the poor judgment on the part of the operators. They would have died even if the operations had not been performed for eclampsia. In 245 cases of eclampsia, where there was no sepsis or very little chance of it prior to the abdominal cesarean section, the maternal mortality was only 24 per cent. It was significant that in fifty cases where operative procedures preceded the cesarean sections the maternal mortality was 48 per cent., the difference in mortality being due not to the eclampsia, but to the sepsis accompanying the eclampsia, a condition which could be avoided once this relation of sepsis to cesarean section was fully realized by the profession. The results of abdominal cesarean section for eclampsia, so far as the fetus was concerned, should be and, as a matter of fact, were, gratifying in the 425 cases. In 217 cases since 1900, where the fetal statistics could be studied, the fetal mortality was only 5.5 per cent. Even this mortality was reduced to 3.7 per cent. in 132 cases where the sections were performed after from one to five eclamptic convulsions. These statistics were quoted to show that the last word had not been said regarding the place of abdominal cesarean section in eclampsia. At last the statistics in over 400 cases had shown beyond a doubt that no one was justified in dismissing the treatment of eclampsia by abdominal cesarean section with a short statement that the mortality was so high as to make it an unjustifiable operation.

**Abdominal Pregnancy with Living Child.**—Dr. J. Shelton Horsley of Richmond, Va., reviewed the literature on abdominal pregnancy with a living child and reported a case. From 1809 to 1912 there were 103 cases on record. Regarding those cases as entirely successful in which both mother and child were saved, and the child living a year after the operation, there were five such cases. The author reported a case which fell within these requirements. The patient was a colored woman in whom pregnancy was supposed to be normal until her physician was called in at about full term. He recognized abdominal pregnancy, as the uterus was empty. Dr. Horsley did an abdominal section and delivered a male child, well formed, and weighing six pounds. The mother made a satisfactory recovery, and a year after the operation both mother and child were well.

**Iodine in the Treatment of Infections and in the Preparation for Surgical Operations on the Generative Organs of Women.**—Dr. J. Wesley Bovée of Washington, D. C., stated that the conditions in which this treatment was applicable were: (1) Acute infections of the vulva, vagina, urethra, and the whole of the endometrium. (2) Acute peritoneal infections with proper limitations. (3) Chronic conditions following infections of these structures and of the tubes, ovaries, and pelvic peritoneum. (4) In pelvic surgery requiring examination manipulations or operations on or through the vagina. (5) In such procedures as required opening the cervical canal or uterine cavity from either the vaginal or peritoneal side. (6) As a routine method of preparation of the field of operation on all these structures as well as the rectum. For several years he had confined the treatment of recent and remote Neisserian infection of the vulva, urethra, vagina, and cervix to the application of iodine. He had great confidence in the efficacy of this remedy when applied early. If the condition might be treated before the infection had passed into the uterine cavity or the gland of Bartholin, it could often be eradicated by one thorough painting of the exposed areas below the uterine cavity. If the first application failed, a second made three days later commonly succeeded. In pelvic surgery that required examinations, manipulations, or

operations on or through the vagina, this plan of local sterilization was far superior to any other he had used. The importance of the vaginal application of iodine was emphasized in the radical operation for cancer of the cervix uteri. The high mortality from infection of the peritoneum as a result of breaking of the specimen during its removal and resulting leakage was a striking feature of the recent report of Wertheim's work in this field. This sad complication was best obviated by the use of the iodine to both the vagina and endometrium, preceded by galvanocauterization, with or without curettage, if excrescences or craters be present. Since the etiology of cancer was not known, he would warn against driving any cancer material beyond the uterus by employing considerable pressure in injecting that organ.

**Which Is the Best Operation for Cancer of the Uterus?**—Dr. HERMAN J. BOLDT of New York stated that vaginal extirpation of a carcinomatous uterus gave a lower primary mortality, particularly the method of vaginal hysterectomy generally employed, than the extended abdominal hysterectomy. It must be conceded, however, that in cancer of the cervix the percentage of recurrences was larger after cancer operations where vaginal hysterectomies were done. When one decided upon vaginal extirpation, the technique devised by Schauta of Vienna, whereby the ureters were exposed and the uterine arteries isolated and tied, so that the parametria might be extensively extirpated, was the method that should find preference. The paravaginal section, which was a necessary accompaniment of the operation, would, if surgical precautions were used, give no more trouble than any ordinary wound. With the paravaginal section one secured satisfactory access to the field of work, which, without it, would be a physical impossibility. Despite its great superiority over the regular hysterectomy, the method of hysterectomy usually employed, it should be limited to obese women, the incipient stages of epithelioma of the vaginal part of the cervix, and to cancer of the body of the uterus, when the uterus was freely movable. It was particularly applicable in the cases of the aged, because of the greater sluggishness of the lymphatic system in persons well advanced in years. Generally speaking, however, the extended abdominal operation should be done unless there was a contraindication for doing such an extensive operation. One could undoubtedly remove more parametrium through the abdominal route. Furthermore, one could inspect the glands and extirpate them if the abdomen was opened, which could not be done when the vaginal route was used. The remote results showed that if the abdominal operation be done properly, the ultimate percentage of recoveries from cancer of the uterus was fully 50 per cent. more than by the vaginal route. But one must really do the extended operation, not the original panhysterectomy first done by Freund for cancer of the uterus.

**Fatal Hemorrhage from Erosion of the Gastroduodenal Artery by Duodenal Ulcers.**—Dr. JAMES E. THOMPSON of Galveston, Texas, had seen two fatal cases of bleeding from duodenal ulcers in spite of the operation of gastroenterostomy. In both cases the ulcer was situated on the posterior surface of the first portion of the duodenum, and in both the hemorrhage which proved fatal came on at a time when it looked as if the patients would recover from the operation. The first patient died thirty-four hours after the operation with all the symptoms of concealed hemorrhage, but as no autopsy was allowed, one could only surmise from the poistion of the ulcer that the gastroduodenal vessel was eroded. The second patient lived forty-two hours after the operation.

Dr. RANDOLPH WINSLOW of Baltimore reported a case of complete anterior dislocation of both bones of the forearm at the elbow.

**Solitary Cysts of the Liver.**—Dr. HENRY NORRIS of Rutherfordton, N. C., reviewed the literature of these cysts, and reported a case.

Dr. DYER F. TALLEY of Birmingham, Ala., reported a case of large cyst of the uterus and reviewed the literature on the subject.

Dr. W. P. CARR of Washington, D. C., described an operation for the correction of flat-foot, which was the result of traumatism.

**A Sign of Diagnostic Value in Obscure Cases of Chronic Appendicitis Elicited by Rectal Palpation.**—Dr. FRANCIS REDER of St. Louis, Mo., stated that in the more obscure forms of chronic appendicitis, where other points had failed, he had been able to make an absolute diagnosis through a point located in the first portion (sigmoidal portion) of the rectum. These cases belonged to a class whose symptomatology did not invite attention to the appendix region on account of the total absence of focal symptoms. In many of these cases pressure at McBurney's point had not given the reflex pain that was expected and usually obtained in a lesion of the appendix of this character, while pressure at Morris' point had proven equally as negative. An absence of these reflexes was usually sufficient to dismiss the thought of an existing appendix lesion. The point in the rectum, however, had invariably given a positive reaction in the presence of a chronically diseased appendix. The part of the rectum concerned in this examination was the first portion. It began at the sacroiliac synchondrosis, usually the left side was entirely covered with peritoneum, and had a mesorectum which gave that portion of the bowel a certain amount of mobility. This mobility was of some value in the examination. Within the lumen of the bowel at the junction with the sigmoid about three and a half or four inches above the margin of the anus, there existed aggregations of circular fibers that formed a valve. This valve was constant, was known as the valve of O'Beirne, and varied but little in its distinctive circular characteristics. This valve served as a landmark and was an important factor in the examination. In making the examination to reach the points, the patient was comfortably placed on the examining table upon his back with both legs flexed. The index finger, well lubricated, was introduced into the rectum, and a search made for O'Beirne's valve. This valve was sometimes reached with some difficulty, especially when it was located high, or when the examining finger was rather short. It was absolutely necessary that the valve be located. Its recognition was readily perceived; the sensation imparted was very similar to that which the examining finger experienced when introduced into the os uteri during the first stage of labor. In size, he had found the valve to vary in some as large as a ten cent piece, and in others as large as a quarter. The valve having been located, the finger was hooked into it and gentle traction made upon the structures to test the mobility of that portion of the rectum. The tip of the finger was allowed to rest within the lumen of the valve, and the patient asked if he experienced any pain. The answer was usually no. Should there be any pain, it was generally referred to the sphincter area of the rectum. By allowing the finger to rest for a short time this pain would subside. After being assured of the total absence of pain by the patient, the tip of the finger was gently pushed upward toward the right iliac fossa, when, in the event of a lesion of the appendix, the finger would touch a point beyond the valve that would cause the patient great pain. As a control maneuver a similar point might be touched by sweeping the examining finger toward the left inguinal fossa, usually with negative results. The accuracy of the diagnostic value of this point had been verified in some two hundred cases. The patients comprising this series gave a period of time when their health was not good ranging from six months to twelve years. After removal of the chronically diseased appendix, the patient was fully restored to health within a period varying from three months to two years.

**A Study of Unilateral Hematuria of the So-Called Essential Type.**—Dr. R. L. PAYNE, JR., of Norfolk, Va., and Dr. WILLIAM DE B. MACNIDER of Chapel Hill, N. C., reviewed the literature on this subject and reported five cases of unilateral hematuria of the so-called idiopathic type, which were relieved of all symptoms by nephrotomy. The authors were inclined to believe that in the majority of these cases of unilateral hematuria the condition was one of chronic inflammation of one type or another, and detailed a series of experiments which apparently excluded as a causative factor certain acutely developing vascular changes. These experiments would, therefore, apparently contravene Klemperer's theory of angioneurotic edema, and also Albarran's idea of a slight lesion of nephritis being a sufficient cause of the unilateral hematuria.

**Suppurative Pylephlebitis.**—Dr. CHARLES R. ROBINS of Richmond, Va., related in detail a case of suppurative pylephlebitis which occurred in his practice in 1911. In this case Van Cott's vaccines were used. In all, twenty-eight doses were given. It seemed to him that these vaccines caused improvement for a time, but finally the patient's abdomen was opened in two places, and it was found the fluid had become purulent. The patient gradually declined and died after an illness of one hundred and fifty days. In view of the fact that this malady was usually rapidly fatal, and that no plan of treatment had yet effected a cure, he thought treatment along this line by vaccines offered the only hope, and the apparent success of these vaccines noted at one time in this case was most encouraging.

(*To be concluded.*)

## Miscellany.

**A Great Physician of the Middle Ages.**—One of the famous Jewish physicians of the Middle Ages was Moses Ben Maimun, commonly known as Maimonides, who was born at Cordova, then one of the greatest centers of Arab culture, in 1135 or 1139. He was educated there, and after wandering about for several years with his family he became physician to Saladin, whose name is well known owing to his relations with Richard Cœur de Lion. Maimonides records that every morning he went to the palace, and if any of the numerous officials and dependents there were ill he had to prescribe for them, getting back to his own house in the afternoon, "almost dying with hunger." There he would find, in his own words, "Jews and Mohammedans, a varied crowd who are seeking my medical advice. There is scarcely time for me to get down from my carriage and wash myself and eat a little, and then until night I am constantly occupied so that from sheer exhaustion I must lie down. Only on the Sabbath day have I the time to occupy myself with my own people and my studies, and so the day is away from me." Maimonides wrote on philosophy as well as medicine. The most interesting of his writings was a series of letters on dietetics written for the son of Saladin, who seems to have been something of a neurotic, suffering from indigestion, constipation, and depression. The rules laid down by Maimonides have become part of the popular medical tradition. In view of the originality claimed by so many minor prophets of the present day for views that are almost as old as disease, it may not be amiss to give a summary of a few of them. "We should eat and drink only when hungry and thirsty, and should be particularly careful of the regular evacuation of the bowels and bladder. The inclination should as far as possible be satisfied at once. A man must not overload his stomach, and should not drink much during the meal, and only of water and wine mixed. Food should be taken always in the sitting position. There should be no riding or walking or movement of the body until digestion is finished. We should sleep for eight hours, and so arrange our sleep that the end of it comes with the dawn, so that from the beginning of sleep until sunrise there should be an interval of eight hours. We should eat what is easily digestible before what is difficult of digestion—the flesh of birds before beef, and the flesh of calves before that of cows and steers. In summer we should eat cooling food, acids, and no spices. Special care should be taken to have regular movements of the bowels. Every medical means should be taken to overcome constipation. Immoderate eating is a poison to men and the cause of many of the diseases that attack them. Most diseases come from eating either too much or unsuitable food. Every week at least a man should take a warm bath. He should not bathe when hungry nor after eating till the food is digested and should bathe the whole body in warm but not too hot water, and the head in hot water. Afterwards the body should be washed in lukewarm water, and finally cold water should be used. Bleeding should not be frequent; it is only meant for serious illness. After the age of 50 there should be no bleeding. Whoever observes these rules of life faithfully will live long without disease, and in the fullness of his years he will die a natural death. Only the healthy should keep these rules. Whoever is ill or a sufferer from any injury or has lost his health through bad habits, for him there are special rules for each disease only to be found in the medical books. Every change in a life habit is the beginning of an ailment." Maimonides rejected astrology and was never afraid to say he did not know anything. He died in 1204, and his thought had a great influence on philosophy as well as medicine.—*British Medical Journal,* January 11, 1913.

**The Doctors of the Sultan.**—The difficulties that beset the Turkish empire and its ruler are at present attracting the attention of the outside world. It is not without interest to learn about the medical attendants at the Porte. These are numerous and belong to various ranks. The chief physician is Dr. Biringi Pasha, next comes Dr. Hechinge Pasha, the third is Dr. Uchingi, and the fourth is Dortingi Pasha. There are many others. While the duty of the medical staff is to visit the infirmary of the seraglio twice a day, the especial task of Dr. Biringi is to look after the health of the Sultan and his favorites. In the case of any grave illness of one of the Sultan's concubines, the visit of the doctor to the harem is made with considerable ceremony. Accompanied by the captain of the eunuchs and by an aged female attendant of the harem the physician is brought to the presence of the patient and inquires briefly as to her illness. If it is necessary to feel her pulse the patient's forearm must be covered with a veil. If any other part of the body must be examined this must also be sedulousy concealed.

An anecdote related of Abdul Hamid conveys an idea of the manner in which the medical practice of the palace is carried out. A daughter of Hamid had an attack of appendicitis. The Sultan, who had not sufficient confidence in the physicians of the palace, summoned von Bergmann from Berlin. But this condition was imposed upon the eminent German surgeon: before the latter would be permitted to operate upon the Sultan's daughter he would have to operate on another case of appendicitis in the presence of the Sultan. This was accordingly done. Even then the Sultan hesitated in granting his consent to have his daughter operated upon. A certain Turkish physician was then called in who promised to cure the girl without an operation. He kept her for a few days on a diet of olive oil and figs. The appendicular pain disappeared and the one who effected this magic cure was given the title of Biringi Pasha.—*Revista Ospedaliera,* December 15, 1912.

**Enthusiasm in Medicine.**—T. F. Reilly notes that there is no other profession in which enthusiasm thrives more easily than in medicine. Every patient is different, every patient is a new disease in himself. There is no room for ennui. When a botanist finds a new specimen, as he rarely does, his enthusiasm and pleasure are unbounded; how much more interesting should be the finding of a human specimen differing from his fellow in structure and disease. This enthusiasm is the best antidote for the blues. Lack of enthusiasm does not inspire confidence. No other profession or vocation offers the same variety of themes as is provided by the profession of medicine. From the spiritual and moral standpoint there is no vocation in which one can do so much good and none in which one can so well relieve pain both mental and physical. To do this effectively the physician should take good care of his own health. The laity believe that he carries some charm to ward off disease. The only charm that he carries is good habits and hygienic living.—"Building a Profitable Practice."

### GENERAL ANESTHESIA BY THE INTRAVENOUS ROUTE.

By WILLIAM FRANCIS HONAN, M.D.,
NEW YORK,
ATTENDING SURGEON TO METROPOLITAN HOSPITAL
AND
J. WYLISS HASSLER, M.D.,
NEW YORK,
ASSISTANT SURGEON, METROPOLITAN HOSPITAL.

LIKE many discarded or forgotten surgical procedures which, when revived, interest the medical profession by the charm of apparent novelty, general anesthesia by the intravenous route seemed to come as a surprise to surgeons and anesthetists who honored our clinics with their presence whenever this method was employed. According to Page[1] Oré, in 1872, was the first to establish the possibilities of this procedure, using chloral hydrate as the hypnotic agent with considerable success in 51 cases. Further experiences, however, showed that either the method or the drug employed possessed certain dangers, and after a few fatalities he discontinued its use. In 1909, Burckhardt,[2] after extensive animal experiments, became enthusiastic over the intravenous method and attempted its use on the human subject, using chloroform at first but soon discarding it for ether, which he found quite as efficient, and much safer. At the Berlin Surgical Congress in 1910, six surgeons of prominence corroborated the success of Burckhardt, Kümmel reporting 90 cases in his own experience, believing that it was particularly useful in aged and cachectic individuals.

Later, Fedoroff[3] of St. Petersburg collected 530 cases from 3 Russian clinics, in which hedonal had been used in the same way and, although the cases embraced all kinds of surgical operation, there were no deaths attributable to the anesthetic. Eight cases of temporary respiratory arrest, however, yielded to simple methods of artificial respiration. Up to this time, the method of induction of anesthesia in this manner was somewhat crude, as Kümmel pointed out, not free from danger, particularly of thrombosis. Burckhardt employed a simple infusion apparatus from which a mixture of a 5 to 7½ per cent. of ether in normal saline solution was allowed to flow through a cannula into a convenient vein, usually the median basilic, until a sufficient narcosis was established to proceed with the operation. The flow was stopped by compression of the rubber tube, connected with the cannula, until the patient began to show signs of returning consciousness, when the solution was again admitted to the circulation, and so on until the operation was completed. Fedoroff and his colleagues used a 0.75 per cent. of hedonal in normal saline solution, in much the same way except that the cannula was entirely withdrawn from the vein to be reintroduced into a fresh one when more anesthesia was required. Kümmel sought to obviate the danger of thrombosis by providing two tanks, one with normal saline and the other containing the anesthetic solution, both being connected with appropriate control stop-cocks and a Y-connection so that, even though the anesthetic solution was cut off, the normal saline flow could be continued, and thus the circulation in the vein at no time be absolutely stopped. This method did not give a smooth, even anesthesia and finally Rood[4] devised a most ingenious apparatus, safe, simple,

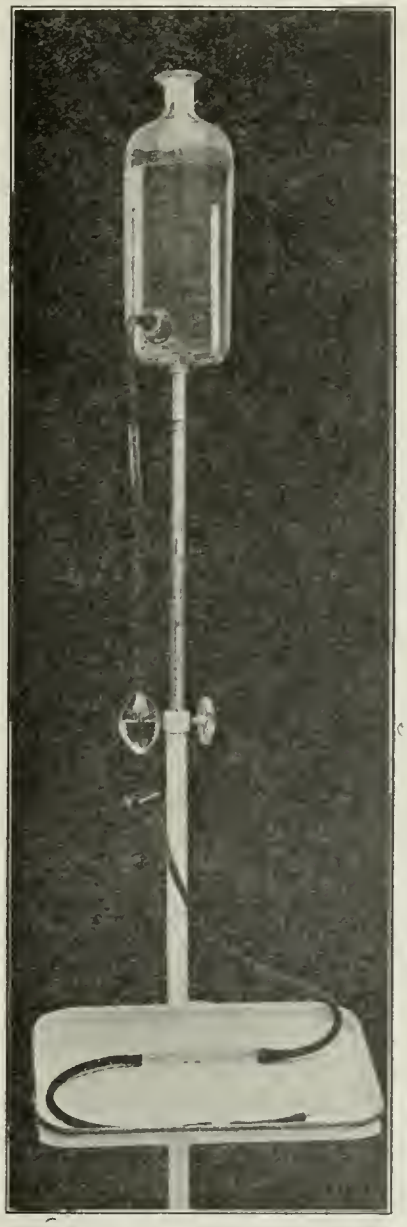

FIG. 1—The apparatus for the intravenous administration of anesthetics.

and efficient, which has answered all the requirements for maintaining a continuous, easily regulated flow, which may be kept at a uniform temperature, and places the degree of narcosis quite within the easy control of the anesthetist.

We have constructed such an apparatus, largely from materials at hand, with a justifiable spoliation of some of our other equipment, which has embodied all of the essential features of Rood's valuable suggestions, so that the use of this method of anesthesia does not necessitate a very expensive outlay.*

It should be understood at the outset that this procedure is not urged to supplant any of the well-recognized forms of anesthesia in general use, nor do we entertain the hope or belief that it will become the method in universal use. We are convinced, however, that, with further experience and development, its efficacy and safety will assign it a definite field of usefulness. In the generally employed method of respiratory anesthesia, some volatile agent is introduced into the circulation by way of the lungs, the rate of introduction being affected by certain variable factors, the energy and depth of the respiratory effort, laryngeal and respiratory spasm, the condition of the bronchial mucous membrane, and the skill of the anesthetist. There are, of course, many other conditions which modify the amount of anesthetic required to produce surgical narcosis in a given subject, but those mentioned are present as variable factors in every case where the indirect or respiratory method is employed. It is manifestly clear that, under these conditions, in every case of anesthesia produced in this way, more of the anesthetic is introduced into the body than is necessary, the excess is stored up in the tissues to be gradually eliminated, a matter of several days duration, with often the unpleasant, if not serious consequences, which mark the toxic effects of the drug employed. The delayed effects of anesthetics, after narcosis and after the patient has recovered from the shock, and other more or less immediate results of the operative procedures are worthy of closer and more extended study. It is reasonably certain, in the minds of most observers, that acute yellow atrophy of the liver (or a poisoning of the hepatic cells and interference with their metabolic activity), injuries to the myocardium, and the developments of a state of acidosis allied to diabetic coma, are occasional late sequences of chloroform administration. The well known irritating effects of ether upon the respiratory apparatus and the kidneys are well understood. The evil effects of any anesthetic do not depend upon the amount taken into the lungs but the amount absorbed from them by the blood, and again the amount absorbed by the tissues from the blood, and especially those tissues of the nervous system which are intimately associated with vital functions.

It must be borne in mind, as pointed out by Buxton,[5] that, if the administration of an anesthetic is kept at the same level, narcosis will deepen, and if the anesthetic is a stimulant, such as ether, the initial stimulation of the nervous system gives rise to an ever-increasing exhaustion. If the anesthetic is a depressant, such as chloroform, its maintenance at the same level of strength will turn depression of function into profound exhaustion. However slight may be the degree of respiratory failure, it leads to diminished pulmonary ventilation, and this to lessened oxidation which, with failing blood pressure, causes the tissues of the body to be enfeebled to the point of being rendered moribund.

The correct interpretation of the situation is the recognition by the anesthetist of the fact that, when once a level of narcosis sufficient for the purposes of the surgeon is reached, very little anesthetic is necessary to maintain that equilibrium once it is established, and that, so long as the tissues are not over-narcotized, the cells will part with the anesthetic and regain their normal physiological status when the administration of the drug is withdrawn.

In the employment of intravenous anesthesia, the agent is directly introduced into the blood, a minimum amount is used, it is maintained there at a certain definite percentage, and its employment can be withdrawn abruptly without storing up in the body reservoirs such excess as may subsequently prove harmful to the patient. In this method the production of anesthesia is very rapid, the preliminary state of excitement is nearly always absent, the patient breathes almost naturally, the color of the skin remains good, and the relaxation and flexibility of muscles are absolutely satisfactory to the operator. The degree of narcosis can be maintained to a nicety and at the completion of the operation the patient often answers questions rationally before leaving the operating room, and returns to bed with better physical signs than before the anesthetic was administered.

It cannot be too strongly urged that, for the successful induction of this form of anesthesia, very careful attention must be given to what are apparently trifling details of the technique. The failure to recognize this fact has been the reason of only partial success in the hands of some of our interested confrères.

For the intravenous use of ether, the patient, having been prepared, is taken, about forty minutes before the time for operation, to the anesthetizing room and placed preferably upon the operating table which is to be used during the operation. A subcutaneous injection of scopolamine, gr. 1/100, atropine sulphate, gr. 1/100, and morphine sulphate, gr. 1/6 is given in one dose, preferably in the loose tissues of the chest or abdomen. From this time until the actual anesthesia is accomplished, it is extremely advisable to keep the patient as quiet as possible so that the administration is begun with the patient in a condition of reposeful relaxation of mind and body. This precaution materially shortens the first stage, induces prompt anesthesia with the least amount of solution, and economy in this direction is much to be desired.

A 5 per cent. solution of ether, with filtered sterile normal saline solution at a temperature of 85° is poured into a reservoir, which has a capacity of 2000 c.c. and which is adjusted on a stand eight feet above the floor level, at which point it remains during the administration. The fluid flows through an indicator (which contains a pipette), then through a warming chamber into a blunt cannula and so into the vein. The indicator consists of a cylindrical or globular bulb of a capacity of from 2 to 4 ounces with an inside pipette, very much such as is used in Murphy's apparatus for proctoclysis. When the apparatus is working properly, the lower half of the indicator is filled with solution while the upper half contains air. The solution flows from the tank through the pipette and drops on the surface of the fluid in the lower half of the indicator. By means of a compression tap,

*The Kny-Sherer Co. of New York has made a very satisfactory apparatus, after our designs, for intravenous infusion anesthesia.

placed below the indicator, the rate of flow can be accurately controlled, and if the fluid in the bulb is kept at a proper level a satisfactory index is furnished as to the rate the solution enters the vein. As ether boils at 98.6°, it is very important to keep the solution below that point, as the agent is so volatile that it usually vaporizes and escapes if the temperature is raised even for an instant above 95°.

Usually the arm furthest from the operator is selected and bound at the wrist to a padded splint which extends under the body to the opposite side, the weight of the body holding it in place. Or the arm may be bound lightly to a splint extending from wrist to axilla and resting on a table of convenient height. This effectively prevents flexion of the forearm. The bend of the elbow is wiped with a 5 per cent. solution of thymol in carbon tetrachloride, which is preferable to the usual iodine application, as it is more effective as a disinfectant, and as it does not discolor the skin, the position of the vein is easily determined. After anesthesia of the skin is induced by one-half of one per cent. solution of cocaine, the median basilic vein is exposed through a small incision one-half to one-third of an inch long, and a double catgut ligature passed beneath it.

Fig. 2.—Induction of anesthesia by intravenous injection.

The distal one is tied and the ends left long and handed to an assistant, who uses it as a tractor. By lifting on both ligatures, the vein is lifted from its bed, and with scissors is incised through about one-half of its diameter. Into this opening in the vein, a small, blunt cannula is introduced and tied with the proximal ligature.

The solution should be administered at a full flow at the beginning, the anesthetist reducing the stream at the appearance of the usual signs of surgical anesthesia. It is quite as incumbent upon the anesthetist to take the usual precautions to secure and maintain an unobstructed air-way and efficient respiratory act, as in the usual method of anesthesia. Ether is rapidly eliminated by the lungs in this method, and, as is true of all methods, efficient respiration prevents accumulation and tension on the tissues, increases its output, and lessens its toxicity. In from one to five minutes anesthesia will be complete and the operation may proceed.

It is highly important, as was noted above, to be economical in the use of the anesthetic solution; the patient should be placed in the appropriate position for the intended operation, the operative field draped, the skin disinfection completed, and the surgeon absolutely ready to make the initial incision when the cannula is inserted into the vein. There is a limit to the patient's tolerance for even salt solution, and it is very desirable that any portion of the period of anesthesia be not wasted upon preparation but reserved solely for the actual operative technique. When the degree of narcosis is obtained which varies somewhat with the nature of the operation, the flow into the vein is reduced by the control-cock just below the indicator. It may be allowed to drip in a very fine stream or at the rate of 40 to 60 drops per minute, the corneal reflex affording a reliable guide for administration. The anesthetist readily becomes acquainted with the effects of the drug by this method, and as narcosis can be absolutely and beautifully controlled, there is no need for any embarrassment to the operator from involuntary muscular contractions. Again let it be urged that careful attention be directed to the maintenance of an open air-way, and as the muscles of the jaws and neck are very much relaxed, the tongue should not be allowed to drop back into the pharynx. It is more important to attend to these respiration precautions than if the patient were being anesthetized by the inhalation method. We advocate a continuous flow in intravenous anesthesia, no matter what agent is employed as the hypnotic, though a few times we have interrupted the stream for a few moments without any appreciable harmful effect. At the conclusion of the operation unless it has been quite prolonged, particularly if ether alone has been used, the dressings should be applied before the flow is actually stopped, as the return to consciousness often comes very promptly and the patient may resist efforts to finish the toilet of the incision properly. No blood changes, different from what occur from intravenous infusion of salt solution plus inhalation ether anesthesia, have been observed in any of our cases. The blood pressure rises slightly with the use of ether in this way—we use it preferably in the old and cachectic patients, avoiding its use in young, full-blooded, or alcoholic subjects.

Oozing is more noticeable, perhaps, in the operative field, and, if the cavity of the abdomen is the seat of the operation, fluid rapidly accumulates there. If extensive adhesions are to be dealt with, the fluid rapidly becomes blood-stained, and there might be instances where this might embarrass and delay the operator, but we have not been so troubled. The patient may be brought from one degree of anesthesia to another very rapidly by the judicious use of the control indicator, and it is well that the operation be entirely finished and dressings applied before the administration is stopped, as the patient returns to consciousness very quickly.

The employment of ether in this way seems almost devoid of danger, from either immediate or remote complications, notwithstanding the fact that the infused fluid must be kept at a temperature not higher than 90°. Ether boils at 98.6° and escapes from the solution as gas, and the failure of some

of my confrères to induce anesthesia, after seeing demonstrations of the method, has been due to the failure to observe this simple physical fact. We have had no case of chill or fever follow 1800 c.c., administered at a temperature of 90°. This is about the only essential precaution in the intravenous administration of ether.

Hedonal, or methylpropyl-carbinol urethrane, is a white crystalline solid stable powder, soluble in water at a temperature of 100°. In doses from 15 to 30 grains, it has been very successfully used as a pure hypnotic. It is, to some extent, a diuretic, does not depress the action of the heart and, in lethal doses, destroys life by respiratory arrest. No fatalities attributed to the use of hedonal as an hypnotic have yet been reported.

For the induction of anesthesia, the drug is dissolved in a normal saline solution at a temperature of 70° to make a 0.75 per cent. solution. The resultant fluid is filtered and brought to a boiling point; we prefer not to boil five minutes, as recommended by Page,[1] as some of the efficiency is lost by volatilization of a certain amount of the compound due to prolonged boiling. The tank is filled, and when ready to begin, the fluid should be about 115°. The same method as used with ether is employed, the fluid being allowed to run in rapidly. Greater caution is necessary with hedonal than with ether, the effect is much quicker, and on the appearance of signs of deep narcosis, the stream is reduced until it flows guttatim from the pipette in the indicator. The patient quickly becomes drowsy, the face flushes or, if the flow is too fast, may be slightly cyanotic, the pupils usually contract, the muscles relax, the corneal reflex is absent, and the patient seems to be in a condition of sound normal sleep, without the noisy respiration of an anesthetic. Observation of the corneal reflex determines the rate of flow which, after a little experience, can be regulated to the satisfaction of operator and anesthetist. After operations lasting from fifteen minutes to one-half hour, the patients often wake quite promptly, but with large administrations they may sleep six to twelve hours, during which time they may be awakened but they readily fall asleep again. The blood pressure always falls with the use of this drug in this way. In one of our demonstrations before the Society of New York Anesthetists, we purposely seleced a patient with a very high blood pressure (186 mm.) which promptly came down to 142 mm., and so remained for several days after operation. In all we have had 78 administrations without a fatality and without a complication worthy of mention, a transient diarrhea in our very first ether case, and a slight bronchitis in a frail subject after the removal of a colloid goiter weighing nearly two pounds. The class of cases has been those that have come in ordinary general hospital service—laparotomies for uterine fibroids, pyosalpinx, ovarian cyst, appendicitis, uterine suspension, hernia, joint resections, arthroplasties, amputation of thigh, bone plating operations, plastic operations on cervix and perineum, removal of laryngeal growth, goiter, extensive secondary carcinomatous glands of the neck, carcinoma of tongue and face, operations for varicose veins, and castration. The case of ovarian cyst was noteworthy—a woman æt. 67, had been tapped 36 times. The cyst wall weighed 15 pounds and, though some of the contents was lost, ten gallons were actually measured. Ether was used in the case, the anesthesia was a perfect success, the patient showing no untoward symptoms at the end of the operation, notwithstanding the sudden withdrawal of so much fluid and the last operation record was comparable to that of a minor operation.

One of us (Hassler) prefers ether on account of its efficacy and safety, but the other one (Honan) favors hedonal as possessing most of the characteristics necessary for this form of anesthesia. It can be sterilized, is stable, capable of accurate dosage, prompt, efficient, reduces blood pressure, and, more important, seems to fulfill the purpose, as expressed in Dr. Crile's idea of anoci-association, of preventing cerebral bombardment by shock impulses. There is no question but that the appearance of the patients after operation indicates that this contention is probably true. It has been suggested that the use of hedonal in this manner may be extremely useful in controlling the convulsions or uremia, particularly of the puerperal type. Its sedative action, its power to lower the blood pressure, and the diluting and eliminating effect of the saline, or preferably an isotonic glucose solution in this instance, opens up a field in speculative therapeutics that might prove of inestimable value.

We have also experimented in five cases with paraldehyde, using it alone and with ether. Ether has always raised the blood pressure from 2 mm. to 20 mm. while, with hedonal, it falls from 10 mm. to 12 mm. One case, as noted above, purposely selected with a blood pressure of 186 mm., dropped to 142 mm. and remained at the lower level for some hours. There have been no evidences of hemolysis, other than occurs in ordinary saline transfusion, or in the respiratory method of giving ether. Hedonal seems particularly well borne so far as the blood picture is concerned. In a subsequent paper, this part of the subject will be particularly discussed.

The time required to produce complete anesthesia ranged from one and one-half to twenty-three minutes with ether, while with hedonal the time was from twelve seconds to four minutes. We kept one patient under ether for one hour and twenty-eight minutes, using 2,100 c.c. of solution (about 3 oz. of ether); another with hedonal, 175 grains in 1,600 c.c. of solution. No case of right heart dilatation was noted, though the Trendelenburg posture was used in cases for which it is adapted. The cases were marked by absence of nausea and vomiting in every instance, comparative freedom from post-operative pain, absence of thirst, rapid restoration of functional activities of the body. The mental status, particularly after the use of ether, is markedly clear, the patients are happy, and those who have experienced other forms of narcosis, express a preference for the intravenous method of anesthesia.

Continued experiences make us think well of paraldehyde 2½ per cent. and ether 3 per cent. in normal saline solution. No preliminary hypodermic medication is necessary, the narcosis is quick, smooth, the color of the patient remains good, and no unpleasant after-effects have been observed. This combination seems to occupy a place between ether and hedonal.

In order to secure a more uniform saline solution, which will be of a definite strength and correspond more nearly to the chemical composition of the blood, we are about to use Ringer's solution.

Through the courtesy of Prof. Baskerville of College of the City of New York, and Dr. James T. Gwathmey, we find that, in water at 60° F., ether is soluble in about eight times its volume and it

should be mixed at that temperature in the tank and should be gradually raised to a temperature of 90° F. in the warming chamber.

In a subsequent article, we hope to present more or less complete records of blood pressure observations, hemolysis, etc., which have been made, with much care and interest, by Drs. Coombs and Patterson, of the Metropolitan House Staff.

## A PRELIMINARY REPORT OF OPERATIONS UNDER EXTRADURAL ANESTHESIA.

By JEROME M. LYNCH, M.D.,

NEW YORK.

PROFESSOR OF RECTAL SURGERY, N. Y. POLYCLINIC.

This method of anesthesia first suggested itself to me when I was making some experiments with Dr. Baldwin of Professor Stockard's staff, with the object of developing a method of blocking the sympathetic in order to obviate shock in the combined operation for cancer involving the rectum and sigmoid. We knew when we began these experiments that this could be accomplished by hypodural anesthesia, but wanted to discover a method which, while as simple, was less dangerous. (Our method of blocking will be described in a subsequent article.)

The essential points to be considered in anesthesia are: First, safety; second, efficiency, and third, a minimum of after complications. Therefore, any method of anesthesia which combines these qualities must of necessity be of infinite value and have a definite advantage over all other means of anesthesia thus far employed. In the limited experience I have so far had with extradural anesthesia, it seems to embrace all the requirements just mentioned. It has also the great advantage, not possessed by other methods, of preventing shock. Its only disadvantage, so far as we can see, is that its field of usefulness is limited to the lower portion of the body, below the fifth lumbar vertebra, but even with this limitation its simplicity, with perfect anesthesia in a region where sympathetic fibers and ganglia abound, and where shock was formerly an unavoidable feature of the operation, places it in the front rank of surgical procedures.

Intraspinal anesthesia, while it meets all the requirements, is fraught with considerable danger to the patient and can be applied only by those who have had a very wide experience. Even in the hands of the most skillful accidents happen on account of some slight disturbance of the spinal or medullary centers. For instance, a certain increase of pressure, even the slightest, has been shown by Carter to be exceedingly dangerous because of the mechanical effect of the increase in the spinal pressure, causing cessation of respiration quickly followed by cardiac inhibition and a sudden fall in blood pressure. There is also the danger of infection to be considered. For these reasons spinal anesthesia has a very limited field of usefulness.

Nitrous oxide, supposed to be the safest of all anesthetics, is very far from being so if one is to judge by the statistics at present available. Heretofore, the belief in its safety has been due in a measure, I think, to the fact that it was very little used and when used was always given by one skilled in anesthesia. Its usefulness is limited, also, because there are a number of contraindications to its use which I will not go into in a paper of this kind.

Ether, the next safest anesthetic, has a mortality of one in ten thousand, with a possibility of postoperative delayed poisoning, with an action on the liver somewhat similar to that of phosphorus.

Chloroform is much more dangerous and has a much higher mortality than ether, and when used with old people under prolonged anesthesia, is likely to be followed by more complications than ether. However, all these anesthetics have served our purposes for many years and their use will not be supplanted by any other methods of anesthesia to any great extent, I fancy. Besides, it will be admitted by all that in certain conditions a general anesthesia is a necessary evil. On the other hand, any method or procedure that will take the place of general anesthesia, even though it has a limited field of usefulness, is bound to be of great benefit to humanity.

Anoci-association, a term coined by Crile to describe any means by which the patient can be placed in the best possible condition to withstand shock, includes cheerful surroundings, suggestion, morphine and hyoscine before operation, etc. Anoci-association has always been practised more or less by surgeons and should be considered as a necessary prophylactic or preanesthesia measure in all cases.

The method which we are about to describe is absolutely free from danger; it insures a perfect anesthesia, prevents shock, and allows of any surgical procedure below the cul-de-sac of Douglas. It can be used in any of the following procedures: cystoscopy and operations on the urethra, prostate, perineum, rectum, and lower extremities.

Before describing sacral anesthesia a brief outline of anatomical conditions is necessary. Piersoll says:

"The spinal cord (medually spinalis) is that part of the central nervous system, or cerebrospinal axis, which lies within the vertebral canal. Its upper limit, where it becomes continuous with the medulla oblongata, is in a measure conventional, since there is no demarcation on the cord itself to indicate exactly its junction with the brain. Accurately considered, the superior limit of the cord may be assumed to correspond with the emergence of the uppermost root-fibers of the first spinal nerve which pass out between the atlas and the skull; this level also corresponds to the lowest strands of the pyramidal decussation of the medulla oblongata and to the upper border of the posterior arch of the atlas. For practical purposes, however, the lower margin of the foramen magnum defines with sufficient accuracy the upper limit of the spinal cord. Below the spinal cord terminates somewhat abruptly in a pointed end, the conus medullaris, that usually ends opposite the disc between the first and second

lumbar vertebræ. The level to which the cord extends inferiorly, however, is subject to considerable variation, very rarely being as high as the middle of the body of the last thoracic vertebra (Moorhead) or as low as the upper border of the body of the third lumbar vertebra (Waring). In the female subject the spinal cord, although absolutely shorter than in the male, extends to a relatively lower level in the vertebral canal. Marked bending of the spine produces slight alterations in the position of the cord, during strong flexion an appreciable ascent of the lower end taking place. The relation of the cord to the vertebral canal varies at different periods. Until the third month of fœtal life the cord occupies the entire length of the canal, but subsequently, owing to the more rapid lengthening of the spine than of the spinal cord, the latter no longer reaches to the lower limit of the canal, and therefore apparently rises, so that by the sixth fœtal month the lower end of the cord lies opposite the first sacral vertebra, and at birth terminates usually on a level with the body of the third lumbar vertebra.

"The Membranes of the Cord. The spinal cord, together with the roots of the thirty-one pairs of spinal nerves, lies within the vertebral canal enclosed by three protecting membranes, or meninges, which from without inward are (1) the dura mater, (2) the arachnoidea, and (3) the pia mater, all of which are directly continuous through the foramen magnum with the corresponding coverings of the brain. The external sheath, or theca, formed by the dura, is a robust fibroelastic tubular envelope, much longer and considerably wider than the cord, that does not lie against the wall of the vertebral canal, but is separated by an interval containing thin-walled plexiform veins and loose fatty connective tissues.

"The Dural Sheath, about .5 mm. in thickness, extends to the level of the second sacral vertebra and is, therefore, considerably longer than the spinal cord. The part of the sac not occupied by the cord encloses the longitudinal bundles of root-fibers that pass obliquely to the levels at which the corresponding nerves leave the vertebral canal, and a fibrous strand, the filum terminale, prolonged from the cord to the lower end of the spine.

"The Pia constitutes the immediate investment of the cord, and supports the blood vessels destined for the nutrition of the enclosed nervous cylinder. The pial sheath is composed of an outer fibrous and an inner vascular layer, the connective tissue of the latter accompanying the blood vessels into the substance of the cord.

"The Arachnoid, a delicate veil-like structure made up of interlacing bundles of fibroelastic tissue, lies between the other two membranes and invests loosely the inner surface of the dura and closely the outer surface of the pia. It effectually subdivides the considerable space between the external and internal sheaths into two compartments, the one beneath the dura, the subdural space being little more than a capillary cleft filled with modified lymph, and the other, the subarachnoid space, between the arachnoid and the pia, containing the cerebrospinal fluid. The spinal cord, therefore, hangs suspended within the tube of dura, surrounded by a cushion of fluid—an arrangement well adapted to insure the nervous cylinder against the injurious effects of shocks and of undue pressure during changes in the position of the spine. Both spaces, but particularly the subarachnoid, are crossed by fibrous trabeculæ and thus imperfectly subdivided into secondary compartments, all of which are lined with endothelium."

We have examined a number of cadavers, and taken measurements at different points to establish, if possible, a fairly accurate method by which the opening into the canal can be located. At first measurements were taken from the posterior superior spine of the ilium to the tuberosity of the ischium on both sides, but the bisection of these lines did not come anywhere near the opening. The next measurements were taken from the posterior superior spine of the ilium to the left margin of the sacrococcygeal joint, and the same on the other side, and we found the opening of the canal, in the majority of cases, to be where these two lines bisect.

The spine of the sacrum is usually bifid, and does not reach within an inch of the sacrococcygeal joint. Under such circumstances the insertion of the needle is a comparatively easy matter. In other cases the opening is close to the sacrococcygeal joint, and the safest plan to follow then is to locate the sacrococcygeal joint and insert the needle at this point and follow the bone closely, and the needle is bound to enter the sacral canal. One can easily tell if the needle has entered the sacral canal by moving it back and forth, when the bony structure will be felt if the needle is in the canal, and if not the needle can be readily felt under the skin. Of course, in a very fat subject it is possible to make an error, but even under these circumstances it can be demonstrated that the needle is in the canal by bending the outer portion inward and trying to pass the point through the skin, when, if under the skin, it will pass out, and if in the canal it cannot pass out. If the needle is very long, however, and it is passed to one side, it is quite possible to pass it through the skin above the crest of the ilium.

The safest method to adopt, especially by those who are not very familiar with this procedure, is to make an incision a little in front of the sacrococcygeal joint, and if necessary extend it until an opening is found. This can be done under local anesthesia.

The point at which the needle is to be inserted is first decided upon. This can be determined by following the sacral spinus processes until they are found lacking. Slightly above this point will be found the opening of the canal. If, as happens in most cases, we have a bifid spine, the ridges can be easily felt, except in very fat subjects. If the canal opens near the sacrococcygeal joint this point is selected. Then, having first determined the point at which the needle is to be inserted, and this is always in the median line, it is painted with tincture of iodine. Next, a little ethyl chloride is sprayed on the skin and a hypodermic syringe, containing a solution of 1-500 cocaine, with an ordinary hypodermic needle, is next employed in order to anesthetize the skin over the area in which the needle is to be inserted, so that a small incision can be made without causing any pain. It is always better to incise the skin in order to obviate any chance of infection.

The following procedure is used in passing the needle. The needle is grasped in the right hand, and the index finger placed close to the point. It is then passed at an angle of about 15° until the bone is reached. The needle is then passed close to the bone until it has been entirely inserted for

about 1 inch. At this juncture it is well to pause and determine whether the needle is in the canal or not. This can be determined, as we said before, by moving the needle back and forth, up and down, and from side to side. If it is in the canal the wall will be found on all sides, and if not the needle will pass readily through the skin.

When the needle is found to be in the canal about 4 c.c. of the same solution is deposited on each side. This is usually sufficient.

After this has been done the trocar is reinserted in order to prevent the escape of fluid, and the needle, with the trocar, allowed to remain in position until anesthesia is established. The reason for this is because if the anesthesia is not established after 15 minutes it may be necessary to inject 1 or 2 c.c. more, and this is made much simpler if the needle has been left in place.

It is important for the fluid to be absolutely sterile and freshly prepared; also of the same specific gravity as the blood in order that it may be readily absorbed.

After anesthesia has been established the needle is withdrawn, and some cotton and collodion placed over the wound. The patient is then placed in whatever position is desirable in order to perform the operation, and the rest of the procedure depends on what particular operation has been undertaken. If a prolonged anesthesia is necessary, urea and quinine may be substituted for cocaine. I have not as yet determined how much urea and quinine is necessary in order to produce complete anesthesia, or what would be the duration of the anesthesia under this process. I shall work this out later on.

We have used this method of anesthesia in seven different cases, and in all but one the anesthesia was perfect and all that could be desired. In the one failure it was done very hurriedly and the procedure abandoned; then a general anesthetic was given because of the nervousness of the patient. We did not inject a sufficiently large amount of the solution, so this case should not be included.

One case in particular was very interesting. The patient was a young man of twenty-three years with a carcinoma involving the prostate and rectum. We were able to dissect the rectum and remove the prostate with absolutely no pain. However, when the dissection was almost completed and we were ready to separate the rectum from the peritoneum we encountered some pain and pronounced shock by pulling on the rectum. He also had severe pain when an attempt was made to cut the peritoneum with the scissors. Before proceeding farther we had to give the patient a general anesthetic in order to complete the operation.

From this case we learned a lesson, namely, that operations involving the peritoneal reflexion are impossible with sacral anesthesia. If I had used my usual procedure of blocking the hypogastric ganglia above I could have completed the operation without further pain. The shock which occurred when I pulled on the peritoneal reflexion was due to pulling on the lumbar and inferior mesenteric plexus of the sympathetic, and to the fact that we had not blocked this point.

The other five cases were operations involving the rectum only, and all were accomplished with the greatest ease to the operator and comfort to the patient. In no instance did we use more than 1/6 grain of cocaine, and that amount was used in the operation which involved the removal of the rectum and prostate. The point of interest in connection with this case is worth mentioning. Before dissecting the rectum free from the urethra and the removal of the prostate, one of my assistants tried to pass a sound into the bladder. Some difficulty was experienced on account of a posterior stricture. After gentle manipulation we succeeded in passing the sound into the bladder, and during all of this procedure the patient had not the slightest sensation of pain or discomfort.

The value of this method, therefore, in cases of stricture of the urethra in hypersensitive individuals in whom it is necessary to explore the urethra or the bladder can easily be understood. Especially will it be found serviceable in old men on whom it is necessary to do a prostatectomy, or with any procedure involving the urethra or bladder.

NOTE.—Since this article was written we failed, in five cases, to find the canal; but since improving our technique we have succeeded in getting perfect anesthesia in the three cases that followed.

57 EAST FIFTY-SECOND STREET.

## EXPERIMENTAL PSYCHOLOGY AND MEDICINE.*

BY H. L. HOLLINGWORTH, PH.D.,

NEW YORK.

DEPARTMENT OF PSYCHOLOGY, COLUMBIA UNIVERSITY.

WHAT I wish to say on my specific topic must be prefaced by three preliminary remarks. First, the psychology which one has in mind when he speaks of "applications" is not the sort of psychology which limits itself to the introspective analysis of the elements of consciousness and the forms and patterns of their combination. The sort of psychology that admits of application is the larger science which occupies itself with the behavior of organisms in so far as that behavior is paralleled by consciousness or is directly conditioned by the activity of the nervous system. Two forms of behavior are to be distinguished in the subject matter of this science of psychology. The one is constituted by the behavior of mental processes and the mechanisms of consciousness; the other, by the motor behavior of the organism and the mechanisms of activity. Under the first topic we study such functions as sensation, imagery, association, feeling, emotion, impulse, etc. Under the second such topics as habit, instinct, attention, fatigue, learning, work, practice, reaction, etc.

In the second place I shall refer throughout not to what professional psychologists have done, but to all work that can properly be called psychology in the light of the definition I have just given. Much psychological work has been done by medical investigators, but their work is none the less psychological because of the mere fact of their medical training. Lester Ward is an eminent botanist, but his many important sociological studies are not for that reason to be credited to the science of botany.

In the third place, what I shall have to say must relate only to the specific contributions of the science of psychology to the foreign fields in question, not to the general cultural contributions arising from increased knowledge, training, and experience along psychological lines.

Further, a distinction is to be made between a

*The first half of a paper on "Modern Psychology in Medicine and Law," read, by invitation, before the Society of Medical Jurisprudence, New York City, November 11, 1912.

science as a body of doctrine or knowledge, the *content* aspect, and the same science as a point of view, a system of technique and procedure, a basis of classification of phenomena, the *methodological* aspect. In some cases the *usefulness* or *application* of a science involves chiefly the content aspect, as when chemistry is applied in manufacturing, mining, illuminating, or in the various arts. In other cases the application may be chiefly one of methodology, as in the application of mathematics and statistics to insurance, finance, navigation, and sociology.

A science, that is to say, is on the one hand a more or less unique method or set of methods of controlling or examining phenomena. On the other hand it is a more or less systematic array of facts, data, and laws, acquired or established by the use of some such methodology. The incidental applications of the science may be based on the methodology, or on the resultant knowledge, or on both. In a discussion of the extrinsic usefulness of any given science it is well to bear this in mind, and any attempt to extend the application of such science should be supported by discernment of the direction in which the possibilities are conceived to lie. A mere ardor to be of service is bound to prove either inadequate or mystifying.

From the point of view of method and from the point of view of content, then, what have been the psychological contributions to law and medicine, and what further serviceableness may we reasonably expect? I may say at once that in so far as law and medicine have profited from their utilization of psychology, this profit has been chiefly by way of methodology and technique. In so far as there has been any interchange of content, psychology has been far more greatly blessed in her receiving than in her giving. Medical clinics and legal practices have been drawn on freely for data, problems, suggestions, and illustrations, and psychology still shows, in many quarters, pronounced anatomical, physiological, and clinical leanings.

The affiliation of psychology with medicine is of necessity a most intimate one, and this has long been recognized. Lotze's "Medicinische Psychologie" on the one hand and Tuke's Dictionary of "Psychological Medicine" on the other, bear testimony to this affiliation. Or we may pair off in much the same way the various text books of physiological psychology, written by psychologists, and the books on abnormal psychology, written for the most part by medical men. The Vienna and Zurich schools of psychiatry make much use of psychanalysis, which, in its various forms, is but an elaboration of classical experiments of the psychological laboratories. On the other hand men whose chief interests are psychological are seeking and being appointed to research positions in connection with many of our leading hospitals. All of these facts indicate that psychology and medicine are, in part at least, joint tenants of some common ground of content or of method. I hope some time to hear a medical man discuss the contributions of his science to psychology.

It has seemed to me that the contributions of psychology to medicine may be presented under five chief headings. I shall briefly point out these five groups, illustrate them, and indicate whether the contribution is chiefly of content or of method.

I. *Psychological Researches on Patients.*—Three subdivisions may be pointed out here:

(*a*) The mental and motor behavior of patients, as studied by psychology, reflects their organic condition. Knowledge of this condition may be useful to the physician, particularly if it is a nervous disorder that is involved. As an illustration of this type of work I may refer to the recent studies by Dr. F. Lyman Wells, of MacLean Hospital, on the behavior of manic-depressive patients in such performances as speed of tapping, speed and quality of association, sensory discrimination, distraction, etc. Interesting correlations are found between performance in the tests and organic condition at various times in the history of the case.

(*b*) Knowledge of the normal types and range of variation in mental processes may prove of great assistance in diagnosis of supposedly abnormal cases, and may be of general use in clinical procedure. As illustration of this field I may cite the work of Kent and Rosanoff on the association reactions of normal and abnormal individuals. A list of 100 test words was arranged, and the free associations to these 100 stimulus words, in the case of 1,000 normal people, were experimentally determined. When the character of these associates was studied it was found possible to make out normal tendencies in the case of each stimulus word, and also a normal range of variability within this tendency. When these associations were classified according to quality, under such headings as rhyme, neologism, perseveration, individual reactions, etc., the association types of normal people could be made out. The same test words were then given to 247 patients, suffering from the various forms of insanity, and these associations similarly studied. Comparison of these results with the results secured from normal subjects, enabled the investigators to draw such conclusions as the following: "With the aid of the frequency tables and the appendix normal reactions, with a very few exceptions, can be sharply distinguished from pathological ones. The separation . . . simplifies the task of analysis and makes possible the application of a classification based on objective criteria. . . . In dementia præcox, some paranoic conditions, manic-depressive insanity, general paresis, and epileptic dementia the test reveals some characteristic, though not pathognomonic, associational tendencies." Further studies of this sort are in progress; they are at once thoroughly psychological and medically useful.

(*c*) Psychological examination may often be valuable in measuring or demonstrating the efficacy of various treatments for abnormal physical condition. I may give by way of example the psychological examination of hook-worm patients now being made by Dr. E. K. Strong. By a series of tests Strong is measuring the mental alertness and capacity of children who are about to be placed under treatment. At the same time he examines in the same way a control group of healthy children living under the same general conditions. After the treatment both groups of children are to be re-examined by the psychological tests and determination made of such change in mental condition as may be produced—in the normal group by mere repetition and normal growth, and in the abnormal group by these factors plus medical treatment for the disease.

These three subdivisions constitute my first heading, "Special Researches on Patients." Such contribution as psychology may be making to medicine in this field of work is chiefly a contribution of content. But the psychological content is used by the medical man merely to reinforce or supplement his own methods and technique.

II. As a second general heading I suggest *"The Psychological Researches on the Influence of Drugs on Mental and Motor Processes."* Here medicine must be said to owe a great deal to psychology. And the chief contribution has been by way of perfected methods. By way of illustration one need only compare the unreliable, roughly made experiments of Kraepelin and his earlier students with recent work by Rivers and with certain rigorously controlled investigations which have been carried on in my own laboratory. The trouble with the earlier workers was that they knew too little about psychological laws, psychological sources of error, and the technical cautions which must be observed in conducting crucial experiments on mental and motor reactions. Later workers have been more familiar with these factors, and they have drawn their knowledge not at all from the field of pharmacology but directly from the psychological laboratory. Four points may be noted as especially important in the improvement of scientific technique in drug experimentation.

(*a*) *The importance of controlled conditions.* This is, of course, a most obvious factor. However, in many sciences the general conditions are so stable and uniform that many of them may be practically disregarded for the purposes of a simple experiment. Thus the temperature of the room, the day of the week, the noon-day menu, the sex of the operator, and a hundred other conditions are irrelevant to the outcome of an experiment in physics. But in a psychological experiment these factors play an important rôle. One need go back only so far as the time of Kraepelin's drug experiments to find men investigating the influence of tea and coffee in the evenings of days on which the subjects of the experiments had taken both strychnine and alcohol, experimentally, at an earlier hour. We now know, and partly as the result of work done in psychological laboratories, that the primary influence of so mild a drug as caffein may persist for twenty-four hours or more.

(*b*) A second important point in technique, the recognition of which is at least in part due to the influence of psychological methods, is the *necessity of a control squad.* You may recall the account of the control group of normal children in the case of the experiments with the hookworm children. In the case of my own experiments on the influence of caffein, a control squad ran through the entire experiment, covering a period of six weeks, taking daily doses, along with the other subjects. But these doses, although this was known to no one but the director of the experiment, consisted of nothing but sugar of milk. This is of course only another point under the general one of controlling the conditions, and it enables the investigator to compare his drug records with records of undrugged subjects acting under the same conditions of practice, excitement, suggestion, interest, ennui, fatigue, diurnal variation, etc. This again is a most obvious point, yet only a year ago I heard a medical expert of repute assert that a certain drug produced congestion of the cerebral blood vessels, because an animal which had been fed on this drug was found to have congested cerebral vessels after having been killed by a blow on the head. A control animal, which should be struck on the head but not fed the drug, seemed not to have been even considered, although the experiment was deliberately planned and in an important connection.

(*c*) The *importance of control doses* may also be pointed out. The medical experiments on drugs, until within quite recent years, proceeded by administering, at a known time, a known drug to a subject who was aware of the whole situation, and who had his own prejudices and opinions, was open to all manner of suggestion, and who was at any rate more or less interested in the outcome of the test, and, perhaps, excited at the thought of taking the drug in question. Yet any change in performance, under these gross conditions, was likely to be attributed to the direct action of the drug. It was not until Feré, a psychologist, demonstrated the stimulating effect of the mere act of swallowing, or, indeed, of simply holding a drink of whiskey in the mouth, thus getting odor, taste, and any conceivable amount of suggestion, excitement, etc., and until Rivers, another psychologist, wrote his illuminating paragraphs on the technique of drug experimentation, that medical experimenters came to realize the importance of the two factors of sensory stimulation and suggestion.

(*d*) The fourth point in technique is concerned with the *standardization of tests.* Many of the tasks set the subjects of drug experimentation before the psychologists addressed themselves to the standardization of series of tests for definite functions or processes, measured processes which varied not only from individual to individual but even from moment to moment or from day to day with a single individual. The much-used cancellation test is an instance of such an ambiguous task. It must be said that a great deal remains to be done in the way of standardization of tests, but the point to be made here is that it is work which must be done by psychological workers, and which when done, will represent a valuable contribution to the equipment of medical workers.

III. As a third general topic I may mention *Psychanalysis.* Here again, so far as psychanalysis is a contribution of psychology, it is purely methodological in character. The psychanalysts proceed on the assumption that emotional experiences and complexes, which persist in an unclear or subconscious way—fears, wishes, etc.—are nevertheless active determinants of action, thought, and feeling. They act chiefly as disturbers; they disturb our sleep by dreams; they disturb our daily life by producing phobias, obsessions, dissociations, amnesias, slips of hand and tongue, etc. Furthermore, by the simple association experiment, skillfully conducted by an experienced analyst, it is claimed that these complexes may be discovered, brought into clear consciousness, and dissipated, and the sufferer thereby relieved. The work of Freud, Jung, Janet, Brill, Jones, and others may be cited here. It must be said that psychologists are by no means unanimous in their reaction toward the claims and interpretations of the psychanalysts. But the lack of unanimity of individual psychologists is one of the things that makes the science interesting. We must say at least that in so far as psychanalysis throws genuine light on the causes, conditions, and prognosis of functional disorders, and in so far as its utilization affords relief which ordinary therapeutic measures fail to give, it represents a real contribution to medical science. And it, again, is chiefly a methodological contribution.

IV. *The Use of Psychological Agents* (Psychotherapy).—This fourth general topic is one on which I might be expected to dilate at great length. It is the one about which most has been written, and which is, I think, quite commonly supposed to con-

stitute the most important direction in which psychology may contribute to medicine. But it seems to me to be, at the present time at any rate, one of the minor issues. Suggestion, hypnotism, reeducation, synthesis, clarification of complexes, association, and dissociation are the words which come to all of you as I read. That some of them are psychological words there can be no doubt. That they represent genuine mental processes, states, or functions, and that psychologists are interested in discovering and formulating their laws, must be granted. But it is equally certain that no little obfuscation has been caused by pseudoscientific writers who have attempted to arouse dramatic interest in certain phenomena of fatigue, automatism, drowsiness, and hysteria, and have drawn into their service in this attempt the occult suggestions which formerly emanated from the words suggestion and hypnotism. As for the terms reeducation and synthesis, they are not, properly speaking, psychological at all, but represent large and practical processes, with little attempt at psychological analysis, description, or formulation. And as for the last two processes, association and dissociation, psychology has done little more than incorporate in its own literature fragmentary clinical pictures and speculations indulged in by medical investigators. The processes intended by the words suggestion, reeducation, synthesis, etc., in the books on psychotherapy really move on the same plane, psychologically, as do such expressions as: Lend a helping hand, give direction, set a good example, give encouragement, provide an incentive, take a little exercise, arrange for new surroundings, jog the memory, etc., etc. All of these phrases, it is true, emphasize the mental functions of a psychophysical organism rather than its physiological processes. This emphasis is, perhaps, responsible for the first two syllables of "psychotherapy." And it follows, of course, that acquaintance with the laws of mental and motor behavior and with the elements, attributes, patterns, and genesis of mental processes is favorable to satisfactory work on this plane, as it is also in teaching children, hunting wild beasts, and selling goods. My point is that the use of these psychological agents does not require any very profound knowledge of the refinements of modern psychology—the contribution of psychology to medicine at this point is not specific in character, but is rather the general contribution to which I referred earlier in this paper. I fell impelled to add that the contribution here will become more and more specific when psychology begins to occupy itself more with *the way in which mind works*, and less with *what is in the mind* at the moment of its operation.

V. The fifth and final field in which I seem to find psychology making specific contribution to medicine may be designated *Determination of the Organic Conditions of Efficiency*. The contribution here is peculiar in that it may often appear to be but a contradiction of the deliveries of medical science. I shall call your attention to but two subdivisions of this general topic—fatigue and periodicity.

(*a*) The investigation of muscular fatigue is so near the border line of physiology and psychology that little need be said of it here. Perhaps the one important point is the fact that psychological studies tend constantly to emphasize the importance of purely mental factors in the production of supposedly muscular inefficiency; such factors as ennui, loss of interest, the inhibitory action of sensations of strain, habit, and the general level of fatigue sensation, etc. The distinction between actual exhaustion and mere cessation of work because of psychic inhibition, a distinction constantly exemplified during psychological investigations of fatigue and work, would seem to be important in medical diagnosis and therapeutics.

With respect to mental fatigue, the net outcome of psychological studies up to date is that the more muscular fatigue is eliminated from a given task the more unfatigueable does the process become. This is often expressed by saying that purely mental fatigue has never been satisfactorily demonstrated. Of course, it is also true that no purely mental process has ever been isolated. There seems to be little doubt that by the cooperation of medical science with psychological investigation information may ultimately be secured concerning the nature and causes of fatigue which will be of service to both fields of work.

(*b*) But nowhere is psychology more at variance with medical science than on the question of the relation between organic periodicity and psychomotor efficiency. By way of illustration of this variance I may refer to the declarations of the periodic inefficiency of women, declarations in which medical and semi-medical books abound. I shall not entertain you with the many available quotations from general writers, but shall present two or three statements direct from the pens of eminent medical men, and contrast these statements with the results of carefully controlled psychological experiment.

Max Runge, a gynecologist of Göttingen, wrote in 1900: "An experienced observer will be able to note many interesting phases of the mental changes in women at menstruation. Even though scientific experiments are as yet lacking, it may nevertheless be stated that a very great number of healthy women are mentally different during menstruation. . . . All demands on her strength must be remitted . . . for several days she is enfeebled."

Icard, writing in 1890, concludes: "The psychical and physical state of woman during the menstrual period seems to me to constitute one of the chief reasons why she should not administer public affairs. Indeed, one cannot depend on a health so fragile and so often disturbed; the errors of judgment and the false valuation so often made at that time prove that women are unable to undertake comfortably and successfully that which should be the exclusive lot of the strong sex. The menstrual function may, especially in the class of the predisposed, induce sympathetically a mental state varying from a slight psychosis . . . to absolute irresponsibility. Such is the proposition which I lay down, and which I shall endeavor to demonstrate. . . . I shall cite in support of my thesis the opinions of the most famous authors.* I shall from time to time let the ancients speak. . . . I have consulted distinguished alienists, father confessors, the directors of convents, superintendents of boarding schools and homes of refuge, midwives, women of the world. . . . I can do no better than resay badly in prose what Alfred de Musset has said so well in verse. . . ." And authors writing as late as 1909 refer to Icard's work as the most authentic and reliable discussion of the subject!

Ellis, although not a medical man so far as I am aware, writes on the basis of considerable familiarity with medical literature as follows: "It is but the

*Meaning the romantic novelists.

outward manifestation of a monthly physiological cycle which influences throughout the month the whole of a woman's physical and psychic organism. Whatever organic activity we investigate with any precision we find traces of this rhythm. While a man may be said, at all events relatively, to live on a plane, a woman always lives on the upward or downward slope of a curve. This is a fact of the very first importance in the study of the physiological or psychological phenomena in women. Unless we always bear it in mind we cannot attain to any true knowledge of the physical, mental, or moral life of women."

Mosher's experiments on blood pressure are often cited in evidence of this periodicity. But the writers who quote Mosher seem not to have observed that the investigator also studied blood pressure in men, and states in the original report: "The daily records of the blood pressure . . . on men and women under similar conditions of life and occupation give curves apparently indistinguishable in character."

In striking contrast with these assertions of periodic psychical changes dependent on organic rhythms, allow me to quote by permission from the manuscript of a recent and as yet unpublished experimental study on "The Alleged Periodic Inefficiency of Women." This investigator has tested, under controlled conditions, four subjects for a period of four menstrual periods, measuring the efficiency with which various mental and motor tasks could be performed. The tests included steadiness, speed of tapping, fatigue, speed of perception (color naming), and association time (naming opposites). The quotation is as follows:

"As is obvious, these results (from so few subjects) are by no means conclusive, but they are suggestive. They show at least what happened in the only cases that have ever been experimentally investigated. The results may be briefly and specifically stated as follows:

"Careful and exact measurement does not reveal a periodic mental or motor inefficiency in normal women. No part of the period is affected except that there is some evidence that on the first day motor ability is slightly improved and involuntary tremor lessened. Physical suffering seems to affect association processes adversely, judging from two instances here recorded where suffering was experienced on the first day. The variability of performance is not affected by physiological periodicity. No regularly recurring period of maximum efficiency within each month is discernible, except that in the tapping test there is an uncertain suggestion that the time of greatest speed is at the beginning of the period. The "cycle" referred to by Ellis and others is not discovered by methods of precision, except the vague suggestion of a regularly recurring maximum of motor speed mentioned just above. No agreement is established between curves previously platted for pulse, blood pressure, temperature, etc., and the curves of the mental and motor traits here tested."

I shall not attempt in this connection to settle the dispute over the question of periodicity in mental and motor capacity as dependent on organic rhythms. Nor shall I consider the reliability of other reputed rhythms, diurnal variations in efficiency, periodicity in men, etc. The important point is that the findings of modern experimental psychology, based on the examination of normal people, are on many of these points much at variance with the generalized clinical findings of medical men.

My general conclusion is, then, that the chief contribution which psychology has made and may be expected to continue to make to medical science is methodological in character. There seem to me to be two principal reasons for this:

In the first place, the experience and training of the medical student are largely clinical. This means that his observation is for the most part of pathological conditions. He may easily fail to acquire sufficient information concerning normal types and the direction, conditions, and range of normal variability. Such knowledge, which might well be partially furnished by adequate psychological training, might at least warn him of the fallacy of generalizing clinical findings.

In the second place, the medical course as it is now offered seems to provide little training in exact and purposive experimentation. An excessive proportion of the student's time seems to be occupied with the memorizing of anatomical minutiæ, the most of which are straightway forgotten, the disciplinary value of which is at least questionable, and the content of which is always accessible in the manuals. It seems to me, for these reasons, that one of the most fruitful contributions which psychology may *yet* make to medicine may be a rigorous, specially adapted full-year course in experimental psychology, which should be incorporated at an early point in the curriculum of the medical school. The content of such a course should be determined largely by medical men, but much stress should be laid on methods and technique of arriving at experimental certainty, avoiding logical fallacies and inductive errors, and of adequately controlling the grounds of inference under circumstances in which very slight factors may play important rôles.

By way of concluding this paper, let me remind you that I began by pointing out the distinction between the method and the content of psychology. I then proceeded to give what must be admitted to be a very incomplete and partial statement of the contribution of modern psychology to medicine. This contribution was found to be for the most part a contribution of method rather than one of content, although useful material of the latter sort was not found to be wholly lacking. The reason for this fact is undoubtedly to be found in the youthfulness of that type of psychology which I have had in mind throughout the greater part of this paper. That psychology is perfecting its methods of examination, control, inference, and verification to a degree that is unusual in the natural sciences may be taken to be a hopeful sign of the wealth of material contribution which may be made to the purposes of practical living, when psychology has outgrown its adolescence.

---

**Uricemic Valvulitis.**—M. Chiray and J. Bailleul state that the heart complications of gout belong to two large categories. These include respectively functional and trophic disorders. The first comprises modifications of rhythm: palpitations, bradycardia, arrhythmia, attacks of false angina; while the second includes manifestations of cardiovascular sclerosis; chronic myocarditis, coronaritis, and valvular lesions of arterial origin. In addition to these relatively frequent complications there are others, more rare, to which the authors give the name "uricemic valvulitis." The lesion consists of an infiltration of the valves with uric acid crystals.—*La Presse Médicale.*

# TREATMENT OF BENIGN PAPILLOMATA OF THE URINARY BLADDER WITH THE OUDIN HIGH-FREQUENCY CURRENT INTRODUCED THROUGH A CATHETERIZING CYSTOSCOPE.*

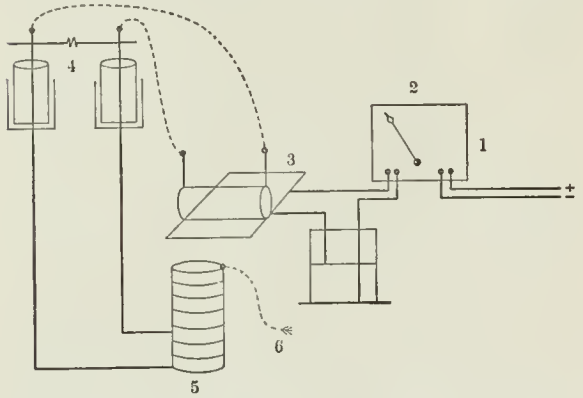
By EDWIN BEER, M.D.,

NEW YORK.

MT. SINAI HOSPITAL.

It is universally admitted that the successful operative eradication of papillary growths of the urinary bladder is very difficult to accomplish. The great frequency of recurrences after all types of operative attack has for years so clouded the clinical picture that surgeons were inclined to accept the statements of Rokitansky and of Guyon, that all papillary growths were clinically as well as pathologically malignant.

In very recent years, due to the excellent work of Nitze, the profession is beginning to realize that the transurethral approach to bladder papillomata gives by far the best results and that the old view as to the malignancy of all papillomata is incorrect. Being firmly convinced of the absolute correctness of this latter viewpoint, *i.e.* that there is a distinct pathological and clinical difference between malign



The High Frequency Apparatus. 1, Represents Source of Current (Street); 2, Rheostat, Meter, Etc.; 3, Induction Coil and Interrupter; 4, Condenser and Spark Gap; 5, Oudin Resonator and Terminal; 6, Electrode Delivering the Oudin Current

and benign papillomata, I turned my attention some four years ago to working out a transurethral technique which would be effective and at the same time much simpler than that employed by Nitze and others who have followed in the lines indicated by him (Casper, Blum, Kutner). My efforts were stimulated greatly by the fact that I had good reasons, both clinical and pathological, to think that benign papillomata were much more frequent than was generally admitted.

Ever since February, 1910, I have been using the Oudin high-frequency current in treating benign papillomata of the urinary bladder, passing my electrode through the catheter tunnel of a catheterizing cystoscope, and applying the current directly to the growth. The method of procedure has been carefully described in the *Journal of the American Medical Association* (May 28, 1910), in the *Zentralblatt fuer Chirurgie* (No. 34, 1910), and in the *Annals of Surgery* (August, 1911). In this as well as in the report presented before the annual meeting, June, 1912, of the American Medical Association, the results obtained up to date by myself and some other surgeons have been brought together.

*Technique.*—The essential instruments for this therapy are: (1) a high-frequency machine with Oudin resonator,* (2) a catheterizing cystoscope, (3) a heavily insulated copper electrode.

To produce the current essential to the therapy discussed in this paper, I have used the high-frequency apparatus manufactured by Wappler. The Oudin current is derived from the resonator, and is unipolar, thus allowing of the use of only one intravesical electrode. The current oscillates very rapidly and is of very high voltage. The source of the original current may be the usual street current. If this does not alternate the high-frequency machine must be fitted with an alternator. The accompanying sketch, taken from de Keating Hart (1908), shows diagrammatically how the Oudin current is generated from the street current.

The Oudin current has been known for some fifteen years and has been used with varying success in a number of skin conditions. Of late it has been used in malignant disease by de Keating Hart. Almost all workers with this current have made use of a spark of varying length holding the electrodes at some distance from the lesion and playing the sparks upon this. Early in my experimental work on skin warts, I saw that direct contact between the current and the electrode was much more effective in destroying the warts than when an air gap was maintained. The cauterizing effect of the current thus used can be easily demonstrated experimentally on a piece of raw meat immersed in water in a pus basin (non-insulated). The point of application of the electrode becomes rapidly white and in a few seconds the cauterization progresses to carbonization. While this takes place hydrogen is freely generated. A current of equal intensity applied through an air gap has no such effect. Moreover, according to the analyses made up to date, metallic copper appears to be regularly present in the tissues at some distance from the point of application when contact is made but not otherwise. Investigations along these lines are not concluded as yet. Up to date it would appear that the current as used in the treatment outlined in this paper has several activities in addition to being a powerful cautery. It is only fair to say that physicists have rather regularly denied this.

In view of the ready handling of the Oudin current and in view of its marked cauterizing effects, it will surely prove of great therapeutic use in a great variety of conditions, not only in the bladder and urethra. In these parts it has proven an ideal cautery in my hands. The applications can be made under the guidance of the eye through cystoscope or urethroscope, and small or large areas can be cauterized as each case demands. In papillomatosis of the larynx I feel sure that it will prove as useful as in the similar vesical condition.

After the bladder has been washed and then filled with distilled water, the cystoscope armed with the electrode is introduced. The electrode is pushed a short distance in among the villi and the current is allowed to play for 15-30 seconds at each application. The nearer the electrode approaches the base of the growth the shorter should be the applications, lest the bladder wall be injured. Moreover, if the electrode touches the bladder wall it causes

*Read by invitation before the Berlin Urological Society, October 1, 1912.

*Instead of the induction coil and interrupter the latest model instrument uses a closed magnetic field transformer ("step-up") which gives more rapid oscillations and can be employed in any room effectively.

pain, otherwise there is no pain. By making repeated applications at different spots the whole growth will be rapidly destroyed, and as it disintegrates it is voided in small pieces, as a rule. This process of separation in very large growths may extend over several months, usually only a few days to a week. As stated, I employed the Oudin current derived from a Wappler machine, usually placing the rheostat vertically, so that half the resistance was thrown into the circuit. If a stronger current seemed necessary I threw out the rheostat altogether. The spark gap in the muffler was made between one-eighth and one-quarter inch. Usually I employed a short gap.

As a rule, I employed the Nitze double catheter cystoscope. In one catheter tunnel I placed the electrode and to the other I attached a tube for irrigation. A direct cystoscope is useful in some cases, in other cases absolutely necessary.*

The electrode (No. VI Charriere) employed is usually heavily insulated copper (at times steel) made by the Wappler firm. As the rubber melts, it must be repeatedly trimmed.

*Applications.*—The applications were made directly to the growth, the electrodes being pushed a short distance in among the villi under the guidance of the eye, and then the current was turned on at various points for 15-30 seconds, the bladder being distended with distilled water. In my early seances I made the treatments rather short. The longest total applications that I have used at one seance aggregated 10 minutes, 30 seconds at twenty different spots. This was an enormous tumor and so long an application surely is not necessary except in such cases. A total of three to five minutes at one sitting will suffice usually. A few days later it should be repeated, provided any viable tumor tissue is visible, as at the original sitting it is impossible to determine how extensively one has destroyed the growth. Treatments are discontinued as soon as the whole growth appears necrotic. The sloughs are allowed to separate spontaneously or helped along with bladder irrigations. After the base is thus exposed (after two to three weeks) it is treated as were the original outgrowths.

*Effects.*—The immediate visible effects are very striking. No spark is seen if the electrode is placed properly among the villi. A spark may be seen if the surface is flat and prevents the electrode from burying itself. While the current is on, gas† is freely generated and bubbles out of the growth. If the point of application is superficial one can readily see blanching of the tissues about the point of application, and at the spot where the electrode's point rested the tissues are blackened. As the electrode is withdrawn from the growth, very frequently it is found to be adherent to the villi, and as it is pulled upon the whole tumor moves with the electrode, which finally comes away with a small mass of tumor tissue baked to its tip. This is only rarely followed by bleeding, and a reapplication of the current at the same spot usually controls this.

After the patient has expelled the necrotic tumor the base may require further brief applications to destroy any tumor residue as stated above. The patients should be carefully cystoscoped from time to time, and if any suspicious areas are visible they should be destroyed at the same sitting. In this way we can hope to obtain excellent and permanent results.

No method which is so destructive of tumor tissues can be absolutely free from danger.

A danger that one can imagine is severe burning or, perhaps, perforation of the bladder wall. With care this should be avoided. As one is working under the guidance of the eye, one ought to know exactly where the electrode is situated before turning on the current, and by adhering to this fundamental point no such damage should be inflicted.

*History of the Method and Nomenclature.*—In the early part of 1909, after purchasing in Vienna the intravesical set of operating instruments made by Victor Blum, for use through the ordinary Nitze catheterizing cystoscope, my thoughts were turned to procuring an intravesical cautery that could be used in the same manner as the Blum instruments. In Vienna I could find no such cautery, and on my return to America I decided to look into the question of using high-frequency currents for this purpose, having previously had some experience with its cauterizing effects on skin warts. I immediately took the matter up with the Wappler firm, where I had bought my high-frequency apparatus, and was thoroughly disappointed when Mr. R. Wappler, the electrical expert of that firm, told me I could not use these currents as I wished, because, first of all, an air gap between the tumor and the electrode was essential, and, second, the current would burn out by cystoscopes. Others whom I consulted, members of the profession who had more experience with these currents in dermatological conditions, told me that Mr. Wappler's views as to the necessity of having an air gap were absolutely correct. Despite this information, I ordered through the Wappler firm a very thoroughly insulated copper (six-ply) electrode so that I might experiment with these currents and test the validity of these expert views. I wasted some time in trying to fit the end of the electrode with a cup-shaped depression which would retain a small amount of air even under water and thus give me a small air gap. In treating warts under water I quickly found that no such gap was essential and that the warts could be readily removed by direct application of the electrode and current to the warts. I then tested my cystoscopes (Nitze type catheterizing—Loewenstein make) and found that they carried the current without in any way interfering with the illumination. I then treated skin warts through the cystoscope under water, and obtained most satisfactory results. I was then ready to employ the method in bladder tumors as originally conceived.

In proposing a new method of treatment it is always well to call it by some short name. As yet I have not been able to think of any name which properly characterizes this method of treatment, as the title of this paper shows. The high-frequency current of Oudin is used, applied through a copper (heavily insulated) electrode under water, and to express all of that in one word seems more difficult than to cure a case by this method. Others have spoken of the method as fulguration, to which I have repeatedly taken exception, as the method is not the same as fulguration (de Keating-Hart, Pozzi). By fulguration is meant the method of using high-frequency currents as suggested by de Keating-Hart, "sideration" being the name originally employed by this experimenter. Pozzi

*Of late I have used the Bransford-Lewis cystoscope as it allows of direct and indirect vision applications at one sitting without withdrawing the instrument. I have also used more recently the Brown-Buerger and Wappler's 1911 model cystoscope (Freudenberg type).

†Outside of the body this gas produced in similar manner appears to be hydrogen.

suggested that it be called fulguration from the resemblance of the long spark to lightning. As de Keating-Hart says (*Interstate Medical Journal,* June, 1910): "Let it suffice to recall that this method consists in an electrosurgical operation divided into two stages. The first stage consists of the operative removal of the tumor, practised, if not extensively (when that is impossible), at least to the limit of the apparent boundaries of the disease, and including therein metastases and infected glands. Then, in the second stage, long and powerful sparkings of great frequency and high tension are applied to the wound thus made." Another striking difference is evident when we contemplate the effects of the current used as indicated above intravesically through water, and compare them with de Keating-Hart's observations. He says: "This method (fulguration) seems to act, not on the neoplasm, but on the soil in which it grows. Mice cancers, when fulgurated, then removed and reimplanted in healthy mice, developed afresh, under conditions identical with those of grafts that had not been exposed to the spark; the neoplastic cell (not destroyed directly by the electric discharge) was then in no way attacked by it as regarded its viability." On the other hand, in the intravesical method described in this paper, the growth is directly destroyed.

I believe these citations ought to make clear that the method here advanced should not be called fulguration. If the method is properly used one seldom sees sparking, and as fulguration refers definitely to the long lightning-like sparks employed in the manner described above by de Keating-Hart and is an excellent descriptive term for a fixed procedure, it would be confusing to apply that term to the therapeutic method that I am here describing, and to call this new method of attacking intravesical neoplasms fulguration.

The current of Oudin has been used for some fifteen years in removing surface growths, and the only novel feature of my method is the use of these currents under water and in the urinary bladder. The resemblance that it bears to the treatment of surface neoplasms is much greater than that which it bears to de Keating-Hart's technique, and it is my belief that for all these reasons it should not be confounded with the very recent development known technically as fulguration.

*Therapy Used at Present in Bladder Tumors, Benign and Malign.*—In this field during recent years there has been great discord, almost all surgeons favoring the transvesical route, a few pleading for the transperitoneal. Only two or three came out warmly for the transurethral route and the operating cystoscope. Of late a new school has come to the fore, saying "Hands off!" (Posner).

If we are face to face with a malignant neoplasm there can be no question as to what procedure should be adopted. The transperitoneal operation recently strongly recommended by Dr. C. Mayo alone promises any result. If this cannot be done, owing to the patient's general condition, palliation and not a cure is the best that can be expected.

When, however, we come to papillary growths which probably are benign in the great majority of cases despite the fact that Rokitansky named them carcinomata villosa, and despite the teaching of the Guyon school, which considers them malignant because they recur so regularly after attempted transvesical excision, then we enter a much debated field. Nitze has shown that he can obtain much better results with the operating cystoscope than anybody has obtained by transvesical suprapubic operation, and he and Sonnenburg* only recently declared that after such transvesical procedure recurrence is the rule. Cathelin in a recent paper admits at least 50 per cent. recurrences after the suprapubic operation.† He sides with Nitze and the operating cystoscope. Whether the results by the transperitoneal route will approach those obtained by Nitze we can not state as yet. Even if they should be vastly superior to those obtained by the suprapubic transvesical route, and just why they should be it is difficult to figure out, it must be evident that the danger of this operation is much greater than that of the Nitze procedure, and that the transurethral is and will be the more ideal in every way. The only obstacle to the wide introduction of this technique has been the great difficulty of manipulating the rather complicated armamentarium and the very frequent sittings that some cases require as well as the occasional postoperative severe hemorrhages.

If, then, as it appears at present, the transurethral route gives the best results and is the least risky so far as immediate outcome is concerned, it is evident that the new method advocated in this paper must measure up with the method of Nitze and the operating cystoscope.

*Results obtained with the new treatment by thirty three surgeons who have either written to me or published on this subject:*

To prepare an up-to-date report I have resorted to the old expedient of sending letters to all the surgeons who might be using this method of treatment.

Almost all the answers were enthusiastically favorable to the new method. One or two answers were favorable, but not particularly enthusiastic. One answer was far from favorable, but in view of the fact that the surgeon in question had never used the method, I think we can pass over his remarks.

Some 187 cases have been treated in America. These were intravesical papillomata. In addition more than twenty cases of urethral papillomata were treated by these same surgeons. Thus their opinions are based on more than 200 cases in which they have tried this new therapy. This naturally represents more than 200 tumors, as many cases have multiple growths.‡ The unanimity of opinion that this new method is simpler and superior to previous methods is most striking, and surely speaks well for the high-frequency current treatment of vesical papillomata. While over 200 cases have been treated in the United States, in France, Germany, and Austria, surgeons have begun to use the method. Up to date I have heard of 28 cases treated in Europe (Heitz-Boyer of Marion's Clinic, R. Kutner, R. Bachrach of Zuckerkandl's Clinic). All are enthusiastic about their results. Heitz-Boyer uses a slight modification of the original technique which I believe is less effective. R. Bachrach uses the same technique as we use in America, whereas Kutner is using the bipolar current.

Not only are these surgeons satisfied with the simplicity and immediate results, but they are so well satisfied with the end result that all are using the method at the present time.

Those who have been using the new method long enough show definite cures running over two years, carefully controlled by repeated cystoscopic exam-

*Bergman, Bruns, and Mikulicz: Handbuch d. Prakt. Chirurgie, 1897.

†Cathelin: Folia Urologica No. 6, 1910.

‡In my 28 cases I had to treat more than 43 papillomata.

inations. All of my oldest cases continue well without recurrence, and several of them have been reexamined more than half a dozen times during the past two years.

The great simplicity of the method, the fact that it can be carried out successfully in an ambulatory manner, its painlessness and its applicability to almost all cases, makes it a method of election with the patient as well as the surgeon.

*Selection of Cases.*—The last point that I wish to emphasize is a most important matter, namely, the selection of cases of bladder growth that should be treated by the high-frequency current method. I am convinced, after careful trying out, that no malignant growth* will be cured by this method. Consequently we must determine as soon as possible whether we are face to face with a benign or malign growth. At times this is fairly easy, but usually it is very difficult. Of twenty cases that I have been able to study microscopically only six showed carcinoma, and judging from the microscopic and clinical behavior of the other fourteen, I feel certain that reliability of the microscopic test cannot be impugned.

To obtain specimens for microscopic study I have used different methods. Often at first examination and treatment a fair sized piece of tumor can be burned off and removed, attached to the electrode, or recovered from washings. Straining of urine after treatment has in three cases given me pieces of adequate size to make a positive diagnosis of malignancy. In some cases one can evacuate through the cystoscopic sheath at the first examination large amounts of tumor tissue which suffice for microscopic study. When all these methods fail I regularly use the Young's rongeur at the second sitting and bite out a large piece, which is almost always satisfactory for microscopic study. Recently I have determined the presence of carcinoma four times by specimens so obtained. If all these methods of obtaining tissues fail, a careful and experienced worker will be able to decide from the lack of clinical result that he is dealing with a growth that does not respond; in other words, he is dealing with a malignant growth. This delay, I am convinced, should be avoided, as early operative excision alone can cure such cases. Early diagnosis of the nature of the growth is therefore absolutely necessary.

Having put aside all the malignant cases, I believe we should try out the high-frequency current in all cases unless the tumor is inaccessible or the patient too intolerant. The size of a growth or the multiplicity of primary growths (nonrecurrent), I consider no contraindication. There are, however, postoperative recurrent multiple growths in which the whole bladder wall is studded, and in these no therapy short of complete cystectomy will lead to a cure. In this type of case the patient will have to decide, as the surgeon offers him but little.

*Cases, Therefore, to Be Excluded from This Method of Treatment.*—1. All papillary carcinomata should be excluded, as malignant cases do not respond. These should be operated on radically by the transperitoneal route.

2. All patients that are intolerant of cystoscopic examination, naturally cannot be treated by the transurethral route.

3. Those few cases in which the growths are inaccessible either with the indirect or direct vision cystoscope, naturally cannot be treated, as well as those (usually) large growths situated at the neck of the bladder that are traumatized by every introduction of the cystoscope and in consequence bleed severely, preventing accurate work.

*Conclusion.*—It is too early to say that the method used in the cases reported will give results as good as those reported by Nitze. It must be evident that the technic here described is much simpler than that employed by Nitze, and it would appear from all the experiences gathered up to date that it will more than rival Nitze's method when end results are compared. The great simplicity of this new method, the rapidity with which large growths are destroyed, the ease with which any trained cystoscopist can carry out the necessary manipulations, all suggest to me that it is the method of the future in the treatment of benign growths in the urinary bladder.

48 West Seventy-fourth Street.

*The only exception I might make would be very small growths that are superficial.

## LITERARY GENIUS AND MANIC-DEPRESSIVE INSANITY.

WITH SPECIAL REFERENCE TO THE ALLEGED CASE OF DEAN SWIFT.

By EVA CHARLOTTE REID, M.D.,

WASHINGTON, D. C.

ASSISTANT PHYSICIAN, GOVERNMENT HOSPITAL FOR THE INSANE.

In the Medical Record of November 23, 1912, there appears under the above heading an article by Arthur C. Jacobson, M.D., in which he refers to a thesis written by me, and published in the April number of the *American Journal of Insanity*. After referring to numerous isolated sentences in the thesis, dwelling at length upon the case of Dean Swift, one of ten cases presented, and dealing with the political situation, and social conditions in Ireland at the time of Dean Swift, and after making a number of dogmatic and unqualified statements in regard to the relation of genius and insanity, he arrives at the conclusion that "the thesis of Dr. Reid is utterly fallacious."

In regard to the thesis above referred to, I would call attention to the fact that it was published in a journal read almost entirely by psychiatrists and neurologists, and I deemed it unnecessary to explain a fact with which Dr. Jacobson is manifestly unfamiliar, namely that manic-depressive psychosis is not a deteriorating one, and that an individual may suffer all his life from occasional attacks of excitement or depression or both, and that in the intervals between these attacks his mentality remains unimpaired to the end. In the thesis in question it is shown that DeQuincey confessed to having suffered from periodic attacks of mental disorder which influenced and at times prohibited the use of his literary talents, that Keats acknowledged that he was "not right in his head" at times, that Mary Lamb had to be confined in a hospital for the insane at intervals during her entire life, that Charles Lamb was an inmate of an asylum for several months, that Cowper had to be treated on several occasions in a private sanitarium for recurrent attacks of mental disorder; that Poe wrote to a friend, "I become insane with long intervals of horrible insanity"; that Francis Parkman gave graphic descriptions of typical attacks of manic-depressive insanity, from which he suffered, and yet all these writers produced works of lasting value.

Dr. Jacobson remarks that "it seems an odd thing

to the writer that a great literature is not emanating from the asylums of the land, if it be true that the relation of genius and insanity is so close." I would remind Dr. Jacobson that the insane are not all confined in "asylums." If he had ever had to deal with the relatives of the insane, he would have discovered that there is a great army of the semi-insane and semiresponsible at large, many of whom are writing literature, painting pictures, and producing inventions. I might also add that of the insane patients under my care at the present time several have produced poems of recognized merit. If the insane were all confined in institutions such literature as Science and Health, The Book of Mormon, the Koran, and other works which have been considered as epoch-making would never have been given to the world. Much of the literature produced by Dr. Jacobson's favorite author, Dean Swift, would, in the present day and generation not be allowed to emanate even from a hospital for the insane, on account of the postal regulations in regard to the mailing of profane and obscene literature.

Dr. Jacobson complains that the writer of the thesis is unable to distinguish between the "insane temperament and actual insanity." If Dr. Jacobson will define the term "insane temperament" and show where the dividing line between sanity and insanity lies, he will confer a lasting favor not only upon an "intellectual plebeian," and a "bourgeoise of science" but upon psychiatrists of all grades. If he can even formulate a satisfactory definition for the word "insanity" he will accomplish a feat which the psychiatrists and psychologists of all ages have been unable to perform.

In regard to Dr. Jacobson's denial of the statement that the psychosis has at times been the motor force which impelled writers to action, I would refer him to numerous instances cited in the thesis, notably DeQuincey's "Confessions of an Opium Eater" which were written in a few weeks. When the proofs were returned, his period of hypomania having passed, he spent six months in trying to correct one volume. Coleridge was interrupted while writing "Kubla Khan," an opium dream, and never could complete the poem. "The Castaway," composed by Cowper, was but the expression of the depressing delusions that followed him to the grave. Poe's "Raven," as well as several of his stories, are descriptions of his hallucinatory experiences.

In regard to the particular case of Dean Swift, dwelt upon at length by Dr. Jacobson, I note that he first makes the statement that Dean Swift was "the sanest man in England." Later he affirms that the Dean suffered from "cerebral neurasthenia" (which may or may not be considered a form of insanity), and later still expresses the belief that he suffered from arteriosclerosis from the age of twenty-three. The last statement, published as it was in a medical periodical, needs no reply. In regard to the diagnosis of "cerebral neurasthenia" I would say that according to White[1] the mild depressions of manic-depressive insanity may so closely resemble neurasthenia that a demonstration of retardation is the only way to differentiate some of the cases, except by the lapse of time, and a study of the course. If Dr. Jacobson can, two hundred years after, make this differentiation he is doing himself an injustice when he affirms that he is not a psychiatrist. Dr. Jacobson's exhaustive discussion of the political situation in Ireland at the time of Dean Swift has no bearing whatever on the subject of the psychosis of the Dean. The fact that Ireland was oppressed was no reason why Swift should pour forth a stream of the most profane and obscene literature that ever emanated from the pen of a supposedly sane man. However, in order that Dr. Jacobson may not be forced to take the opinion of a "tin-horn critic" or a "lover of the outré," and to show that the writer of the thesis is not the only one lacking in that sense of humor necessary to appreciate the writings of Swift, I shall quote the opinions of writers whose judgment in literary matters might compare favorably even with that of a *real* critic.

Sir Walter Scott says[2] "He is licentious in his satires, and transgresses the bounds of purity and delicacy." Speaking of Gulliver's Travels he adds, "Even a moral purpose could not justify the nakedness with which Swift sketches the horrible outlines of mankind degraded to a bestial state." Thackeray[3] says, "He goes through life tearing like a madman." Speaking of Swift's "Modest Proposal," referred to by Dr. Jacobson, he says, "Could Dick Steele or Goldsmith or Fielding in his most reckless moment of satire have written anything like the Dean's famous 'Proposal.' The Dean has no softness, and enters the nursery with the tread and gaiety of an ogre." Leslie Stephen[4] says, "A morbid interest in the physically disgusting is shown in several of Swift's writings. Some minor pieces which ought to have been burned simply make the gorge rise. It is idle to excuse this on a ground of contemporary freedom of speech. His contemporaries were heartily disgusted. The objection to Swift is not that he spoke plainly, but that he brooded over filth unnecessarily." Taine[5] says, "He dragged poetry not only through the mud but into filth. He rolled in it like a raging madman, and enthroned himself in it, and bespattered all passers by." W. H. Davenport Adams[6] says, "It cannot be said of Swift that he has written a line by which a man can be made better and purer; he has contributed nothing to the world's treasure of love and truth and wisdom. No great man, it might be added, ever so wallowed in filth." John Churton Collins,[7] speaking of certain poems, says, "Nothing so purely diabolical had ever before emanated from man." Speaking of Swift's libel of Pope he says, "It is the very alcohol of hatred and contempt. Its intensity is the intensity of a monomaniac." "To find any parallel to such pieces as the 'Ladies' Dressing Room,' 'Cassinus and Peter,' 'On Corinne,' 'The Beast's Confession,' &c., we must go to the speeches in which the depraved and diseased mind of Lear runs riot in obscenity and rage."

It may be that the same sense of humor which causes Dr. Jacobson to smile when he reads my statement that the industry of the victim of manic-depressive insanity must be spasmodic, and to laugh at the statement that the manic-depressive is unable to adapt himself to his surroundings, enables him to enjoy the humor of Dean Swift. If he were at all familiar with the life history of Swift he would know that his industry was above all things spasmodic. Stephen[8] says, "Swift worked as he seems always to have done, slowly and intermittently." Roscoe[9] says of him, "He was a rapid writer, by fits and starts." From the time he published his "Tale of a Tub" in 1704 to 1710 he did not publish a line. Speaking of this period Collins says, "These five years (1705 to 1710) form perhaps the most unsatisfactory period in Swift's life. He passed his mornings in scribbling pamphlets which he never

published, his afternoons were spent in dancing attendance on the Whig ministers, and his evenings in gossiping with Addison and Addison's friends in coffee houses." Durng the year 1709-1710 he shut himself up at Laracon and avoided intercourse with anyone except Addision. From 1714 to 1726 he remained in Ireland, and nothing was published by him during this period. In a letter to Gay he complains of suffering from a severe depression. He describes his occupation as follows: "I read the most trifling books I can find, and when I write it is upon the most trifling subjects. I procrastinate more than I did 20 years ago, and have several things to finish which I put off to 20 years hence."[10] From the time he wrote Gulliver's Travels, 1727, to 1737, he wrote nothing for publication.

If ever there was a man who was unable to adapt himself to his surroundings it was Swift. He was dissatisfied with everyone, every place, and everything. His college course was marked by constant violations of the rules. While a student in Trinity, from November 14, 1685, to October 8, 1687, he was punished seventy times for infringement of the rules. The examining board pronounced him dull and insufficient and refused to pass him. Finally he was granted a degree "Speciali Gratia." According to Swift himself his object in writing Gulliver's Travels was to vex the world,—"to embody in allegoric form the hatred and disdain with which he personally regarded all nations, all professions, all communities and especially man, as man in essence is." He described Ireland, the land of his birth, as "a wretched, dirty dog hole and prison, of which he could only say it was a place good enough to die in."

In regard to the insanity or sanity of Dean Swift, Dr. Jacobson states that Sir William Wilde, after a study of the available data, declared that there was no proof that Swift had ever been insane, and that his peculiarities in later life were due to the ordinary decay of nature, and adds, "The opinion of this eminent Irish physician is practically conclusive." Dr. Bucknill,[11] in speaking of Dr. Wilde's essay on "The Closing Years of Dean Swift's Life," which was published in 1849, says, "This little work would have rendered further discussion needless if medical science had stood still since its publication." Dr. Bucknill's diagnosis of Ménière's disease is based entirely upon the facts recorded in Swift's Journal to Stella, and his letters in which he complains of suffering from "giddiness, deafness and ringing in his ears." What this disorder really was it is impossible at this date to say, but to one who is accustomed to dealing with the depressed phase of manic-depressive insanity, taken in connection with the extreme emotional depression and other symptoms described in his letters, his affliction suggests the disorders of sensation producing pain and discomfort, complained of so often at regularly recurring intervals by these patients.[12]

Dean Swift's associates and those who came in contact with him daily recognized that he was insane. His conversation and actions while a frequenter of Button's Coffee House, London, caused him to be called "the Mad Parson," a name by which he was known throughout England. A maid at an inn where he was staying, seen by Dean Swift scraping a piece of mutton, and of whom he inquired as to how many maggots she found, replied, "Not so many as there are in your head, sir." The Dean's sense of humor does not appear to have proved equal to the strain, for Scott relates that he became furiously angry at this retort, and reported the maid to the landlady. While dining at the house of a friend, Swift once discovered a small hole in the tablecloth. He enlarged the hole and insisted on eating his entire meal through it. During his periods of hypomania which alternated with his depressions he showed the typical exaggerated ego, exaltation, and expansiveness of the manic-depressive. Collins says the liberties which he took with his social superiors were such as to be scarcely credible. On one occasion he sent the Lord Treasurer to fetch the Secretary of State from the House of Commons, "For I desire," he said, "to inform him with my own lips, that if he dine late I shall not dine with him." The purposeless graphomania which existed at these times has already been referred to. The margin of his Burnet was scribbled over with execrations of the Scots "Most damnable Scots, Scots hell hounds, Scotch dogs, cursed Scots still, hellish Scotch dogs, &c."

Biographers appear to be unanimous in the opinion that Swift suffered from some form of mental disorder: Roscoe, speaking of the Dean in early life, says, "A recurrence of a disorder attributed by Swift to a surfeit of fruit that induced a coldness of stomach, giddiness, and momentary loss of recollection, symptoms of the same disorder with which his uncle Godwin died, attacked him." It might be added here that Swift's Uncle Godwin died insane. Craik[13] speaks of Swift's "Brooding melancholy" while in his twenties, and adds, "It had its root and groundwork in mood and character, and derived strength and confirmation in a congenital malady from which he suffered. This was caused by a structural malformation near the brain that dulled his hearing, produced fits of giddiness and uncontrollable depression, and eventually overcame his reason, but as yet the attacks were only intermittent." Samuel Johnson[14] says, "The disease of Swift was giddiness with deafness, which attacked him from time to time, began early, pursued him through life, and at last sent him to his grave deprived of reason." Collins, speaking of Swift's early life, says, "But unhappily the mind and body of the youth on whom these favors had been bestowed, were so diseased that what was intended to benefit served only to irritate and distress him. Fancied slights, and imaginary wrongs ulcerated his soul with rage and grief." Adams, speaking of Swift's refusal to live with the woman he is supposed to have married, says, "We may conjecture that he shrank from the dread possibility of communicating to another generation the hereditary taint of mental disease of which he was conscious in his own person."

The last years of Swift's life have been graphically described by his biographers. Thackeray describes him as "alone and gnashing in the darkness." Scott pictures his condition as one of "violent and furious lunacy." Stephen says that in 1741 he had to be placed in restraint. In 1742 he was declared insane by a royal commission, and guardians to his person and estate were appointed. Collins says, "As his intellect decayed his irritability and ferocity increased. Day after day he paced his chamber as a wild beast paces its cage, taking his food as he walked, but refusing to touch it as long as anyone remained in the room. His state was horrible and pitiable beyond expression." "For two years before his death he never spoke." Adams says, "A fit of frenzy followed and continued for months. He then sank into the situation of a helpless chargeling. His gloom was deeper and more

constant than that of Cowper." Mrs. Whiteway wrote November 22, 1742, that five persons could scarcely hold him from tearing out his eyes. Bucknill states that he suffered from convulsions for thirty-six hours prior to death, and that a plaster cast made after his decease showed a right-sided hemiplegia. All these symptoms Dr. Jacobson may attribute to the "ordinary decay of nature," but to my mind they spell very clearly arteriosclerotic dementia.

Literary critics appear to agree that the kindest way of explaining Swift's rage for profanity and obscenity was to call him insane. Bucknill says, speaking of the poem, "The Legion Club," "Its animation seems occasionally to verge upon absolute insanity." Collins says, "He appears to have been drawn by some strange attraction to the contemplation of everything which is most offensive and most humiliating in our common humanity. It was of the nature of the morbidity which tortured Rousseau. His writings and correspondence exhibited a mind perpetually oscillating between unutterable despair and demoniac rage." Stephen says, "His indulgence in revolting images is to some extent an indication of the diseased condition of his mind, perhaps of actual mental decay." Adams says, "He has written whole pages of unpardonable bestiality, unpardonable if we refrain from the conjecture that they were inspired by that diseased brain of his, against which he strove so manfully, and yet so unavailingly." In regard to Gulliver's Travels he adds, "The satire is written with trenchant vigor, but the reader shrinks from a fierceness that amounts almost to savagery. I cannot but think, however, that its coarseness can be attributed to a diseased brain rather than a depraved heart." That Dr. Jacobson should wish to deprive the Dean of the only possible excuse which these writers can give for his seeming depravity is a matter of surprise, and can be explained only by supposing that the Doctor believes insanity to be a disgrace, an idea which had its root in the ancient belief that the insane were possessed of a devil. It seems almost impossible to inculcate into the minds of the laity, and even make clear to the medical profession, the fact that a person who suffers from an attack of mental disorder may be no more culpable, and have no more cause for shame, than one who suffers from an attack of appendicitis.

That Dean Swift was not without insight is shown by several of his letters and sayings. At the time he was made Dean of St. Patrick's he could not have been considered other than successful as well as famous. Yet, at that time he wrote to Miss Vanhomrigh, "I was horribly melancholy while they were installing me, but that begins to wear off and change to dullness." Writing to a friend at another time he says, "At best I have an ill head and an aching heart." While walking with a friend one day he remarked, on seeing a tree, the uppermost branches of which were withered, "I shall be like that tree, I shall die at the top," and we have every proof that his prophecy came true. From the foregoing quotations we must conclude that Dean Swift's insanity was recognized by those with whom he associated, by biographers and literary critics, by a royal commission appointed to decide his mental condition, and finally by himself.

## THE NEW CHEMISTRY AND THE NEW MATERIA MEDICA.*

By HERMANN HILLE, Ph.D.,

CHICAGO.

MEMBER AMERICAN ASSOCIATION OF CLINICAL RESEARCH; MEMBER AM. ASSO. FOR THE ADVANCEMENT OF SCIENCE; HONORARY MEMBER SOUTHWEST MISSOURI MEDICAL SOCIETY.

Those who have followed materia medica for the last twenty-five years as impartial and unprejudiced observers cannot help but note, with increasing concern, the almost hopeless chaos and utter confusion into which it has been drifting, and are not at all surprised at the growing nihilism in the ranks of thoughtful practitioners.

When we examine into the causes of this unsatisfactory condition, one factor seems to stand out most prominently, viz., *a general lack of knowledge as to the primary cause of disease.*

An exact knowledge of the primary cause of disease would at once lift the uncertain art of healing to the dignity of an exact science. It would provide a more natural and rational basis for prophylaxis and give rise to a simplified and ordered materia medica. Fortunately there are many facts in modern science which illuminate the path, and admit of rational conclusions toward a satisfactory solution of this all important problem.

In a paper read before the Chicago Medical Society, February 15, 1911, the writer arrived at conclusions which were later supported by what would appear an overwhelming evidence in an article published in the Medical Record, June 15, 1912, and the *Chicago Medical Recorder,* October 15, 1912, entitled: "Facts of Modern Science, and Their Value in the Prevention and Cure of Disease."

Of these conclusions two are of special value for the purpose of this paper, viz., (1) The primary cause of disease, from a purely physical viewpoint, is chiefly mineral starvation; (2) Minerals in inorganic form cannot be utilized by the human organism as directly and effectually as can true organic minerals.

Time and space do not permit to give here the facts and reasons supporting these conclusions. They have been carefully stated, together with the references, in the publications just mentioned. To those treatises the reader is respectfully referred for detailed information.

If it be a fact that the primary cause of disease is mineral starvation, then it follows that the minerals must hereafter occupy a much more prominent place in materia medica than they are occupying at the present time. If it be true that minerals in inorganic form cannot be utilized by the human organism as directly and effectually as can true or-

*Read at the fourth annual meeting of the American Association of Clinical Research, New York, Nov. 9, 1912.

ganic minerals, then it follows that the mineral remedies must be supplied in organic form.

What is the organic form? The answer to this question will become apparent as we proceed.

Organic chemistry designates as "organic" any "compound, substance or radical containing carbon."

This definition is arbitrary and manifestly absurd because, if consistently applied, all of the carbonates, as of sodium, potassium, and calcium, must be classed with "organic" salts.

The original meaning of "organic" is: Pertaining to objects that have organs, pertaining to the animal and vegetable kingdoms; resulting from, or exhibiting characteristics peculiar to, animal or vegetable life and structure.

*The basis of the inorganic world is the crystal. The basis of the organic world is the cell instead of the crystal.*

The destructive effects of inorganic remedies have long been recognized, and efforts have been made to overcome their undesirable features. As a result a flood of so-called "organic" salts were brought to the attention of the physician, often accompanied by grossly exaggerated claims as to their therapeutic action and freedom from undesirable effects. It is now generally conceded that, with few exceptions, these so-called "organic" salts are not much more efficient, if at all, then the purely inorganic mineral salts.

The medical literature abounds with corroborative evidences, with the general effect that the much abused term "organic" has lost its true significance, and many physicians, as well as chemists, have, therefore, come to the conclusion that there is no pronounced difference between "inorganic" and "organic."

It seems to be an inherent tendency of human nature to swing, like a pendulum, from one extreme to the other. To offset this tendency let us, without bias or prejudice, analyze the causes of the disappointing behavior of so many so-called "organic" combinations of minerals, and, if possible, find a remedy.

All physical nature is divided into two great worlds of matter, the inorganic and the organic. The inorganic world of matter is generally known as the mineral kingdom. The organic world of matter includes the vegetable kingdom and the animal kingdom.

We know that the substance of each kingdom serves as food for the next higher kingdom, and that in the process of digestion it is converted or transformed into substance of the higher kingdom.

Thus the minerals supply the food of plants, but not in their crystal or unorganized form. In the process of becoming food the mineral must be raised from its unorganized condition in crystal form to the form of vegetable tissue. Hence, plants possess the power of converting or transforming mineral matter into vegetable tissue. Or, expressed in different words, plants raise inorganic matter to the state and condition of true organic substance.

The animal, like the human, cannot utilize minerals in crystal form as food, because it is not able to transform such mineral matter into animal tissue, the two being separated by a great gulf of condition, which is occupied, or bridged, by the vegetable kingdom. To become available to the animal the mineral must first become vegetable, that is, the inorganic must become organic. In other words, the vegetative process is provided by nature to bridge the gulf between the crystallized mineral and the tissues of the animal organism. After being lifted, or raised, to the higher condition of the organized vegetable tissue, the animal can easily raise it to the still higher condition of animal substance, and thus assimilate it without difficulty.

We are now able to understand why inorganic minerals alone are foreign matter to the human system; why their remedial effects are largely counterbalanced, and often outweighed, by their destructive effects; and why the minerals must become organic before they can serve as food and remedies.

Chemical analysis reveals the fact that the organic world is composed of the same chemical elements that are found in the inorganic world. From the viewpoint of chemistry of today, therefore, the difference between inorganic and organic is not chemical in character.

On the other hand, everybody knows that inorganic matter is different in structure and condition from tissue substance.

*Organic substance, therefore, is an allotropic* modification of inorganic substance.*

For example: Diamond and charcoal, in a purely chemical sense, are the same, viz., carbon. They are allotropic forms of the element carbon. The diamond is a crystalline or inorganic, and charcoal an amorphous or semiorganic form of carbon.

Marble is one of the inorganic, crystalline forms of calcium carbonate, and some of the organic, colloidal forms of the same substance occur in the shells of eggs and oysters and in the valuable pearl.

Metallic silver is the crystalline or inorganic form, and Carey Lea's allotropic silver is an amorphous, colloidal, or semiorganic modification of the same metal.

The yellow, poisonous crystalline phosphorus is an inorganic form, while the nonpoisonous, red phosphorus is an amorphous, semiorganic modification.

Countless other examples could be cited. In fact, the results already obtained in colloidal chemistry make it safe to proclaim that every known substance can be raised from the crystalline into the colloidal form. But the examples given here would seem sufficient to illustrate the fact that the crystalline form is characteristic of the inorganic world, while the colloidal form is characteristic of the organic world.

Since the middle of the last century chemists, biologists, and physiologists have been engaged in the study of colloidal substances. Michael Faraday, Berzelius, Francesco Selmi, Carey Lea, and especially Thomas Graham, were the pioneers in this fascinating and fruitful field, which has grown into such dimensions within the last ten years that it has become a new branch of chemistry and bids fair to outgrow all the rest of chemical science and become the chemistry of tomorrow. Many workers in this field—and their number is increasing almost daily—are beginning to sense the fact that colloidal minerals are Nature's bridge to purely vegetable substance. But they do not dare to proclaim their

*From the Greek, *allos*, other, different, + *tropos*, way, manner, guise. Allotropy: the property which certain chemical elements have of existing in two or more distinct forms, each having certain characteristics peculiar to itself. "Allotropism being interpreted as some change of molecular arrangement, this frequency of its occurrence among the components of organic matter is significant as implying a further kind of molecular mobility."—H. Spencer, Prin. of Biol., § 1.

conviction openly as yet, not being prepared to make the demonstration.

Some colloidal minerals, like dialyzed iron, colloidal silver, colloidal mercury, etc., are known to all physicians. They are known also to be less poisonous than their purely inorganic cognates. But many of them are not true organic substance yet, being merely stages of transition from the crystalline inorganic to the cellular organic. This has been demonstrated within the last few years with the aid of the microscope and the ultramicroscope.

Just as it is possible to produce of the same substance almost any size of crystals, from the largest macroscopical to the smallest microscopical, so is it possible to produce of the same substance practically any size of colloidal particles, from the largest to the smallest ultramicroscopical.

The microscope and the ultramicroscope reveal the facts that all particles of matter are in a state of motion or vibration, and that microscopical particles vibrate slowly while the much smaller ultramicroscopical or colloidal particles vibrate rapidly.

The crystalline inorganic is coarse in particle and slow in vibration. The cellular organic is fine in particle and rapid in vibration. The amorphous-inorganic and the colloidal semiorganic are intermediary steps.

*And here we are face to face with Nature's evolutionary principle.* The evolution from the crystalline inorganic to the cellular organic appears to be accomplished by means of refinement of particles and increase of vibratory activity.

We can now account for the fact that many so-called organic salts are not better as remedies than their inorganic forms. In the light of the foregoing the explanation is very simple. Those so-called "organic" salts are not organic in the true sense. They are merely loose associations of an inorganic element, or salt, with an organic substance, which fact alone does not make the inorganic organic. A transformation of the crystalloid component into the colloidal form is required to make the compound organic in the true sense. In other words, to be rightfully entitled to the designation "organic" the mineral element, or compound, must be: (1) raised to the colloidal form; and (2) combined with a native organic substance, such as protein, carbohydrate, fat, etc.

For this true organic form of minerals the writer, in a previous paper, adopted Faraday's term "vitochemical," to distinguish them from merely so-called "organic" minerals.

Briefly recapitulating:

1. Inorganic matter and organic material are the same in essence but different in form and structure.

2. The inorganic world is crystalline. The organic word is colloidal.

3. The inorganic is coarse in particle and slow in vibratory activity. The organic is fine in particle and rapid in vibratory activity.

4. Mineral bodies, *in organic form,* are an essential constituent of food and of the animal organism, and are of vital importance in the prevention as well as the cure of disease.

5. Crystalline, or inorganic, minerals are not fit to serve as food or remedies for the animal organism. They will, therefore, eventually be eliminated from materia medica and replaced by vitochemical, or true organic, minerals.

6. The smaller the particles of a colloidal mineral, and the higher their rate of vibration, the better is it assimilated and adapted as a remedy.

7. Many of the so-called "organic" salts are not organic in the true sense because all, or part, of the compound is still crystalline and not colloidal.

8. The old chemistry, whose days are numbered, is unable to differentiate between inorganic and organic.

9. The new chemistry has not only made clear the difference between inorganic and organic, but also sheds its light upon a problem which in the old chemistry was one of the most profound mysteries, viz., *Nature's evolutionary principle.*

This principle, and its relation to chemistry, the writer will make the subject of another treatise.

## THE NEGLECT OF ORAL TREATMENT IN INFECTIOUS DISEASES.

By C. EVERETT FIELD, M.D.,

NEW YORK.

In considering the treatment of all of the acute infectious diseases and many of those chronic, we may wonder to find some of the most important details overlooked. Did we carefully investigate the processes of autoinfection that are constantly originating in the mouths of our fever cases, we would surely give oral hygiene the full attention it deserves.

Of course it is not necessary for me to detail the long list of pathogenic bacteria commonly found in the nasopharyngeal cavity or to magnify the broad expanse of mucous membrane with its folds, lacunæ, and canals, the teeth in their varied stages of necrosis, all of which serve as perfect soil for infection and incubation. We are familiar with the fact that fully two-thirds of the diseases affecting mankind are contracted through the membranes of the nose and throat. How common are the symptoms of gastrointestinal fermentation in the course of fever cases. It is not necessary for me to point to the fact that foods we so carefully select for the patient, the milk we pasteurize, pass to the stomach and intestine through a mouth which may be laden with millions of microorganisms. Furthermore, to find a collection of sordes on the teeth of any fever case should be classed as evidence of neglect.

Granted, then, that we agree as to the common danger herein stated, is it not strange that so important a part of treatment as oral sanitation should ever be neglected? And yet, all too frequently this seems to be the case. Sometimes the lapse is due to the fact that we take it for granted the nurse is caring for this part of the treatment, or possibly we ourselves have failed to recognize its full importance.

On equal footing with therapy and diet, if not in advance of them, should come the minutest instructions relative to the care of the mouth. Direct the nurse or attendant to cleanse the teeth of the patient at least twice daily and to rinse or swab out the mouth before and after each feeding with a stimulating alkaline antiseptic solution. By following this course rigorously in all cases of serious illness you will be many times repaid as you note how few will be the complications, how seldom will come the signs of self-infection, and how gratefully your treatment has been received by the patient. His food tastes better, his appetite continues to be good and assimilation is carried on to the utmost.

## LESSONS FROM THE RECRUDESCENCE OF DIPHTHERIA IN GERMANY.

THE severe outbreak of diphtheria in Germany during the past few years furnishes a complete denial of the assertion that the affection is becoming milder under general sanitation. In the discussion of Reiche's paper (an abstract of which was recently published in the MEDICAL RECORD), which is to be found in the *Berliner klinische Wochenschrift*, December 30, many opinions were expressed by the leading clinicians of Hamburg. Schottmüller stated that without the necessity for any apology for the results of serum treatment, the facts stand out prominently that antitoxin should be injected early and in large doses and also intramuscularly. A certain percentage of mortality is the result of septic complications and cannot be modified at all. Thüngel, who saw only severe institutional cases, relied on serum entirely, and his mortality curves show its success. A measure of its efficacy is seen whenever the percentage of laryngeal stenoses and tracheotomies is low, as in the author's material.

Hegler contrasted the mortality of the early nineties—thirty-two per cent.—with the thirteen per cent. of the past few years. In the past four years and a half 61 nurses and twelve physicians in the Eppendorf Hospital had contracted the disease with but two deaths, in both of which there were elements which showed that the conditions were exceptional (one patient already had a myocarditis, while the other died of pneumonia of the ordinary type). This is a document attesting both the severity of the epidemic and the efficacy of the serum, but it shows also that prophylactic injections are not infallible. Kissling said that a study of the results of first day injections would convince any one of the specific power of the serum treatment; also that it is only wasted effort to give it after the third day. Schroeder mentioned the special malignancy of the epidemic at Altona. The highest mortality was 23 per cent. in 1909, after which it fell to 17 per cent. The mortality was unusually high after tracheotomy cases.

Kellner described the epidemic in an institution for the feeble-minded, where there was an almost absolute control of the material. There were 107 cases with but three deaths. This low figure was due largely to routine daily inspection of throats with resulting early diagnosis and early serotherapy. Rumpel, in commenting on this report, said that it should be remembered that feeble-minded children are specially resistant to infectious diseases which no doubt has something to do with the very low mortality. Both he and Reiche mentioned unusual mortality after first day injections. Instead of being zero, as in ordinary statistics, it went to 5 per cent. in some material of the past few years.

## ALCOHOLISM IN FRANCE.

IN some countries the consumption of spirituous beverages appears to be decreasing, although statistics relating to the question are, perhaps, not altogether reliable. When trade is bad and money is scarce less alcohol is drank, but, as a rule, when business revives and money is plentiful drinking increases. It used to be said that the drink bill of a nation was a fairly good index of its prosperity. In the case of Great Britain it has been stated frequently of late that spirit drinking is not nearly so evident as formerly. In other countries, however, there has been no marked tendency in this direction. In the United States figures seem to show that drinking is not decreasing, while so far as France is concerned alcoholism exhibits progress rather than decline. The Paris correspondent of the *Medical Press and Circular* states in the issue of January 15, 1913, that alcoholism, tuberculosis, and criminality are greatly on the increase in France, the two latter as direct consequences of the former, and in direct proportion to the consumption of intoxicating drinks. The statement is made that the number of deaths provoked annually in France by alcoholism, either directly or indirectly through heredity, exceeds 100,000. Furthermore, alcohol is responsible for the production of many of the immense number of cases of mental diseases which occur in France. In 1865 there was consumed in France 19,206,044 gallons of alcohol, and 13,984 cases of lunacy were under treatment, while in 1907, when the consumption of alcohol had almost doubled, the number of insane had increased to 71,547, of which 10,000 had been hard drinkers. The number of crimes likewise is shown to have increased in direct ratio to the increase in the use of alcohol. And lastly, Dr. Sicard de Planzoles is authority for the assertion that of all the European armies the one which suffers the most from maladies which tend to indicate a condition of feeble resistance of the race is the French army. The decrease of resistance is attributed to the extension of alcoholism.

If these reports be true, and it may be presumed that in the main they are true, then France provides a striking object lesson on the evil effects of alcohol on the human race. France is rich and prosperous and France is notorious for the large consumption of alcohol. If prosperity brings in its train the wholesale use of alcohol with its manifest and manifold ills, then material prosperity is not to be desired. National decay, mental and physical, is too high a price to pay for the accumulation of riches. The most hopeful sign of the situation, for after all France is by no means the only country in

which so-called prosperity and alcoholism go hand in hand, is that the public conscience everywhere is becoming aroused with regard to the alcohol question, and that steps are being taken to investigate and to try to remedy the existing state of affairs in the most intelligent manner possible. Undoubtedly, one of the most powerful factors in bringing about a change is education through the public and medical press.

## INTESTINAL STASIS.

The paper on intestinal stasis read by Mr. Arbuthnot Lane at the Congress of Clinical Surgery held recently in New York has given an impetus to the consideration of the subject. Probably there are as many cases of indigestion in this country as anywhere in the world and probably, too, a large number of these are due to intestinal stasis. The arrest of normal peristaltic movements is responsible for many complaints and may be the starting point of some grave diseases. The commencing symptoms are dyspepsia and constipation, and in course of time the whole system becomes poisoned by the toxins thrown off by putrefying food, and the sufferer bids fair to sink from asthenia and emaciation. A notable feature of this condition, referred to by Dr. Murray Leslie in the *Medical Press and Circular,* Dec. 25, 1912, is the enormous preponderance of cases occurring in the female sex, and another somewhat remarkable point is that it is frequently associated with enteroptosis. Leslie, although at one time sceptical, is now thoroughly in agreement with Lane as to the presence and significance of the various adhesions and kinks described by the latter, and also believes that the short circuiting operation is the most certain and effectual mode of relieving the condition.

While short circuiting may seem heroic treatment even for obstinate constipation, the author holds that it is safe and effective. He thinks, therefore, that it is better to have recourse to this radical treatment for intestinal stasis than to leave the patient in a miserable state of suffering and chronic invalidism rendering life almost insupportable and so lowering the resistive power of the tissues, owing to the effects of autointoxication, as frequently to endanger the life of the individual from intercurrent diseases, such as pneumonia.

## AMBARD'S METHOD OF DETERMINING RENAL INSUFFICIENCY.

Widal and Javal have introduced into the routine of laboratory methods of examination the determination of the urea content of the blood. M. Ambard has gone a step further. By making a simultaneous determination of the amount of urea in the blood and the amount in the urine, he calculates the ratio between the two amounts, and regards this ratio as the test of renal function. In a recent communication in the *Bulletins et Mémoirs de la Société de Médecine de Paris,* December 28, 1912, H. Carrion and C. O. Guillaumin describe Ambard's method and report the favorable results they have obtained in its clinical applications.

Ambard has shown that in the healthy individual there is a constant relationship between the urea content of the blood and the urea content of the urine. In organic and functional derangements of the kidney this relationship is changed, and the extent to which the ratio differs from the normal content indicates the degree of renal impairment. Without going into the methods by means of which the amount of urea in the blood may be determined, it will suffice to point out that the normal ratio between the urea of the urine and that of the blood has been calculated to be 0.070. This is the normal content. In proportion as the kidneys are impaired this figure is increased. Thus the tendency to a condition of uremia would run parallel with the increase in the urea ratio. The functional capacity of the kidneys is calculated as inversely proportional to the square of this ratio. Thus, in an individual in whom the urea ratio is 0.140, the urea content of the blood is double that of an individual subsisting on an equivalent diet. But in the case of the former the renal capacity is calculated as equal to only one-fourth of the renal capacity of the latter.

## The Fixation Abscess, Its Indications and Technique.

A method of treatment that reminds one of the use of the seton of former days, is described in the therapeutic applications of the so-called fixation abscess. J. Carles, in the *Journal de Médecine de Bordeaux,* January 5, 1913, states that one is justified in resorting to this method of treatment in various forms of pneumonia, in typhoid fever, puerperal infection, rheumatism, and septicemia. The method consists in the injection into the cellular tissue of one cubic centimeter of spirit of turpentine. The site of injection is preferably the outer side of the thigh, the loin, the lumbar region, or the deltoid region. If after the lapse of twelve to twenty-four hours the reaction is slight or absent, the injection may be made at another point. The absence or feebleness of the reaction is an indication of the failure of the defensive forces of the body, and suggests an unfavorable prognosis. On the other hand, the rapid appearance of intense inflammatory manifestations at the site of the injection provides a good prognostic omen. It is pointed out that the rapid development of an infiltration that makes one think of the development of a diffuse phlegmon should not create any alarm. On the contrary, there occurs a coincident disappearance of the symptoms of the original infection. The fixation abscess is fully developed on the fifth or sixth day following the injection. There need be no haste in incising it, for the contained pus is sterile, provided the injection has been made under aseptic precautions.

## The Microbiology of Variola.

Certain pathologists throughout the world have long regarded the germ cause of smallpox as firmly established. But others deny the existence or significance of the supposed discovery, and all are aware that no practical conclusions have ever been deduced therefrom—and a really practical discovery in this field would nearly revolutionize pathology for obvious reasons. Recently before the Medical Society of Halle A. S. Fraenken summed up our knowledge of this subject to date (*Münchener*

*medizinische Wochenschrift,* January 8). Guarnieri's corpuscles have continued to gain ground over an interval of many years. Wasielewski has followed them up in the rabbit's cornea for thirty generations, and from the thirtieth he successfully vaccinated a child. We have not yet succeeded in cultivating the germ *in vitro,* but attempts made to show that the cytoryctes is not a specific organism have also met with failure. More recently Paschen, Fraenken, and others have found an organism common to variola and vaccinia, but its relationship with the cytoryctes is obscure. There are large clumped forms of the latter which do not have a bacteria-tight filter, but it is known that there are younger forms which can traverse such an impediment.

## News of the Week.

**Isolation Hospitals.**—The great need in New York City for hospitals for the treatment of contagious diseases was made manifest recently by the death of a six-months old baby who died of pneumonia on North Brothers Island after having been removed from the Post-Graduate Hospital because of the development of measles. The Board of Estimate a year ago made an appropriation for the purpose, but the objection of real estate owners has made even the purchase of a site impossible, and nothing further has been done. A special hospital for the treatment of measles, provided for some time ago, will be ready shortly, but its usefulness will be limited to the Borough of Manhattan, and the Bronx and Queens will still be without accommodations of the sort, necessitating the removal of patients to the Reception Hospital and thence to the island. The Public Health Committee of the Academy of Medicine has protested against this delay in providing the necessary hospitals and has declared the prejudice against them as dangerous to the neighborhood, to be without foundation.

**Smallpox in New York.**—Smallpox in mild form has been reported as epidemic in a number of widely scattered towns in New York State, including White Plains, Tonawanda, Niagara Falls, Corning, and Mechanicsville. Local health officers have been instructed by Commissioner Porter to enforce vaccination and strict quarantine.

**Nurses to Holy Land.**—The first step in an educative campaign of district nursing in Palestine was taken recently when the Daughters of Zion sent two trained nurses to that country. These two, the forerunners of a prospective corps, will devote themselves primarily to the needs of the women and children.

**Home at Otisville.**—The Urania Society of Otisville, N. Y., recently petitioned the State Board of Charities for permission to establish a home, adjoining the municipal sanatorium at Otisville, in which to care for the wives and children of tuberculous patients.

**State Medical Library.**—The Director of the New York State Library announces that the medical reading room in the library was opened to the public on January 15, with about 12,000 books on its shelves available for consultation and for lending. The library receives between five and six hundred domestic and foreign medical periodicals which are on file in the reading room. The hours at present are from 9 to 6 daily, and on Tuesday and Thursday evenings until 10. Medical books may be borrowed for two weeks, by any licensed physician in the State, full-time instructors in medical colleges, members of hospital house staffs, registered or certified nurses, and other persons offering suitable credentials. When possible, the library lends its books through local libraries or schools, all transportation charges to be paid by the borrowing library or individual.

**Post-Graduate Dinner.**—The Directors and Faculty of the New York Post-Graduate Medical School held their annual dinner at Delmonico's on January 30. Some two hundred physicians were present and addresses were made by Chief Justice Riddell of the High Court of Ontario, and by Mr. Bourke Cockran, who defended the rule of "the highest fee to the richest patient, and all others in proportion."

**Poison from Gloves.**—A shopkeeper of Paris has been sued by a woman customer, who claims damages to the amount of 12,000 francs, on the ground that her blood has been poisoned through the wearing of a pair of gloves which she had purchased.

**Physicians Protective League.**—Many physicians in New York have recently been invited to join an association with the above title, whose object is the correction of "abuses that tend to demoralize our profession," the most important being stated as the "dispensary abuse." It is claimed that thousands of people, able to pay for medical advice, receive free treatment at the clinics, and that this constitutes a flagrant injustice.

**New Laboratory Opened.**—The new physiological laboratory of the Polhemus Memorial Clinic in connection with the Long Island College Hospital was opened on January 29. The laboratory, which occupies one large room in Polhemus Memorial Building, is fitted with the latest and best appliances for students' work.

**Personals.**—Dr. Alvah H. Doty, formerly Health Officer of New York, has been appointed medical director of the Employees' Benefit Fund Committee of the American Telephone and Telegraph Company.

Dr. Rupert Blue, Surgeon-General of the United States Marine Hospital Service, in speaking before the members of the Fifteen-Year Club of the Mutual Life Insurance Company in New York on January 29, described the work of the service in stamping out bubonic plague in and about San Francisco and in Porto Rico.

**Vetoes Sterilization Bill.**—Gov. Fletcher of Vermont recently vetoed the bill passed by the State Legislature, providing for the sterilization of defective criminals.

**Pure Water on Trains.**—The Treasury Department issued from Washington on January 29, regulations prohibiting the supplying of any but "certified pure" water on trains and steamboats in interstate commerce. The regulations require further that all water containers be scalded at least once a week, and that any ice used in cooling the water must also be "certified pure." The requirement of individual drinking cups on common carriers engaged in interstate commerce was made by the Public Health Service some time ago.

**Courses in Hygiene Urged.**—The Efficiency Society, which met in New York recently, adopted resolutions advising the establishment of thorough courses in industrial hygiene in every medical and technical school in the United States. Copies of the resolutions and an accompanying letter will be sent to the dean of every such school in the country

outlining such courses and asking consideration of the possibility of establishing them.

The subjects suggested include sanitary inspection, mechanical and clerical work and their physiological and psychological effects, prevention of accidents and treatment of accidents, disease and its prevention, fatigue and its causes, industrial legislation, the relation of the employer to the physician and the relation of the physician to the employee, the latter including the physical examination of the employee and his instruction; the relation of the physician to the State and municipality, including the reporting of work, accidents and diseases, and the economic and social results already obtained in the prevention of accidents and disease.

**Death Rate Falls.**—During the week ending January 25, there were in New York 1,461 deaths, the death rate per thousand being 14.19, as compared with 1,564 deaths in the same week of 1912, when the death rate was 15.77. During the week there were but two deaths ascribed to typhoid fever. The mortality from January 1 to 25, was one-half point below that of the corresponding period of 1912.

**Extensions to Mt. Sinai.**—Plans for improvements and additions to Mt. Sinai Hospital, New York, costing $1,350,000 in all, have been prepared and half of the amount necessary has already been subscribed. The proposed additions include a pathological building to house all the laboratory work of the institution in pathology, bacteriology, chemistry, etc., two wards of one hundred beds each, dormitories for the nurses and other employees, and a special building for the children's services.

**Explosion in Laboratory.**—An experiment in one of the laboratories of the Rockefeller Institute for Medical Research in New York on January 30 resulted somewhat unexpectedly in an explosion which wrecked the apparatus, destroyed a quantity of chemicals, and blew out a partition between two rooms. Fortunately, no one was injured and the fire which followed was quickly put out by the laboratory employees.

**Cocaine Sellers Sentenced.**—Two men, brothers, one a druggist, the other a dentist, were sentenced on January 30 in Brooklyn to fines of $1,000 each and to imprisonment for having sold cocaine illicitly. In the case of the druggist, who pleaded guilty to the charge of having sold 140 ounces of the drug during the past two years, a sentence of one year's imprisonment besides the fine was imposed, while the dentist, who pleaded guilty only to an attempt to sell cocaine, received a sentence of imprisonment for half the time.

**Hospital Pensions.**—A bill recently introduced into the New York State Legislature provides for a pension fund for physicians and employees of New York City hospitals, to which each person concerned shall contribute one per cent. of his monthly pay.

**Charitable Bequests.**—Bequests of $40,550 each to Columbia University, Mt. Sinai Hospital, and the German Hospital and Dispensary are provided for in the will of the late Mr. Augustus Openhym of New York, who died last April. It is directed that the bequest to Columbia be known as the Openhym fund and that it be used for research into the cause, prevention, and cure of cancer.

**Medical Licenses Issued.**—At a recent meeting of the Oklahoma State Board of Medical Examiners, licenses to practise medicine were granted to eight applicants who had successfully passed the examinations of the Board. Four other applicants from Tennessee, Kentucky, and Texas were licensed by reciprocity.

**Society of Sanitary and Moral Prophylaxis.**—A stated meeting of this society will be held at the New York Academy of Medicine, on Thursday, February 13, at 8.30 P. M. The general subject for discussion will be "The Matter and Methods of Sex Education Other Than Instruction in Schools." The speakers will be Dr. Eugene LaF. Swan, Miss Nellie W. Smith, Miss Laura B. Garrett, and Mrs. Mabel M. Irwin. Among those who will discuss the papers will be Dr. Ira S. Wile, Dr. Thomas D. Wood, Dr. Rosalie Slaughter Morton, Dr. Mary Sutton Macy, and Miss Harriet D. McDaniel.

**Conference on Infant Mortality.**—The National Association for the Prevention of Infant Mortality and for the Welfare of Infancy, of England, will hold a conference on infant mortality at Caxton Hall, Westminster, on August 4 and 5, 1913. The conference will be divided into two sections, administrative and medical, which will sit simultaneously.

**New York Physicians' Mutual Aid Association.**—The forty-fourth annual meeting was held on January 21, when announcement was made that the membership of the association had reached nearly 2,300 physicians, and that the capital fund, including all assets, amounted to about $87,000. The previous officers were re-elected for the ensuing year as follows: *President,* Dr. W. F. Mittendorf; *Vice-Presidents,* Dr. W. C. Phillips, and Dr. Joseph W. Ingalls; *Secretaries,* Dr. Edward Davis and Dr. Edward S. Peck; *Corresponding Secretary,* Dr. W. B. Jennings; *Treasurer,* Dr. Daniel Lewis. The following trustees were re-elected to serve from 1913 to 1916; Dr. David P. Austin, Dr. Ward B. Hoag, and Dr. Heinrich Stern. The Association was incorporated in 1868, and among the original incorporators were Dr. David P. Austin and Dr. Mark Blumenthal, both of whom were present at the annual meeting.

**The Homeopathic Medical Society of the State of New York** will hold its sixty-first annual meeting at Albany on Tuesday and Wednesday, February 11 and 12, under the presidency of Dr. Willis B. Gifford of Attica. The Secretary is Dr. Bert B. Clark, 200 W. 86th Street, New York City.

**Wholesale Appendicitis.**—According to a recent report from Philadelphia, twenty-nine boys, inmates of the St. Francis Industrial School at Eddington, Pa., were operated upon for appendicitis within the past ten days. Sixteen appendectomies were performed in one day and the others at intervals in the succeeding nine days. The cause of the epidemic, according to the same report, was the overeating of cheese.

**Medical Society Elections.**—BUTTE COUNTY (CAL.) MEDICAL SOCIETY: Annual meeting at Chico on January 14. Officers elected: *President,* Dr. P. L. Hamilton; *Vice-President,* Dr. T. P. Reardon; *Secretary-Treasurer,* Dr. Ella F. Gatchell.

STARK COUNTY (O.) MEDICAL SOCIETY: Annual meeting at Alliance on January 21. Officers elected: *President,* Dr. A. J. Hill, Canton; *Secretary-Treasurer,* Dr. C. A. Lamont.

LONDON COUNTY (TENN.) MEDICAL SOCIETY: Annual meeting at Lenoir City on January 12. Officers elected: *President,* Dr. G. M. Burdett, *Vice-President,* Dr. J. G. Eblen; *Secretary,* Dr. J. T. Hickman; *Treasurer,* Dr. W. T. Foute.

CAMERON COUNTY (TEX.) MEDICAL SOCIETY:

Annual meeting at Brownsville on January 22. Officers elected: *President,* Dr. Harry K. Loew; *Secretary-Treasurer,* Dr. H. L. D. Kirkham.

Little Kanawha and Ohio Valley Medical Association: Annual meeting at Parkersburg, W. Va., on January 21. Officers elected: *President,* Dr. W. S. Link; *Vice-Presidents,* Dr. W. S. Stille, Dr. Deerfield, and Dr. Frank Keever; *Secretary,* Dr. Marvin R. Stone; *Treasurer,* Dr. W. H. Sharp.

Italian Medical Society of New York: Annual meeting on December 27. Officers elected: *President,* Dr. P. Virdone, Brooklyn; *Vice-Presidents,* Dr. A. Carini and Dr. J. W. Perilli, New York; *Treasurer,* Dr. G. de Maffutiis, New York; *Secretary,* Dr. D. Petillo, New York; *Corresponding Secretary,* Dr. G. de Yoanna, Brooklyn.

Philadelphia County (Penn.) Medical Society: Annual meeting at Philadelphia on January 15. Officers elected: *President,* Dr. Charles A. E. Codman; *Vice-President,* Dr. M. Howard Fussell; *Associate Vice-Presidents,* North Branch, Dr. Jesse O. Arnold; South Branch, Dr. John D. McLean; Kensington Branch, Dr. Joseph A. Moore; West Philadelphia Branch, Dr. G. Mason Astley; Northeast Branch, Dr. Samuel Bolton; Northwest Branch, Dr. George A. Cameron; Southeast Branch, Dr. Simon Wendkos; *Secretary,* Dr. William S. Wray; *Assistant Secretary,* Dr. Arthur H. Hopkins; *Treasurer,* Dr. Edward A. Shumway.

Langlade County (Wis.) Medical Society: Annual meeting at Antigo on January 4. Officers elected: *President,* Dr. G. W. Moore; *Vice-President,* Dr. G. H. Williamson; *Secretary-Treasurer,* Dr. J. C. Wright.

Stephenson County (Ill.) Medical Society: Annual meeting at Freeport on January 9. Officers elected: *President,* Dr. Charles L. Best; *Vice-President,* Dr. J. A. Poling; *Secretary,* Dr. J. Sheldon Clark; *Treasurer,* Dr. Nelson C. Phillips.

Sangamon County (Ill.) Medical Society: Annual meeting at Springfield on January 13. Officers elected: *President,* Dr. Daniel M. Ottis; *Vice-President,* Dr. Charles D. Wright; *Secretary-Treasurer,* Dr. H. C. Blankmeyer.

Goshen County (Ind.) Medical Society: Annual meeting at Goshen on January 9. Officers elected: *President,* Dr. E. E. Ash; *Vice-President,* Dr. F. M. Freeman; *Secretary,* Dr. W. B. Page; *Treasurer,* Dr. H. W. Eby.

Baker County (Ore.) Medical Society: Annual meeting at Baker City on January 7. Officers elected: *President,* Dr. W. L. Parker; *Vice-President,* Dr. Thomas J. Higgins; *Secretary-Treasurer,* Dr. C. M. Pearce.

King County (Wash.) Medical Society: Annual meeting at Seattle on January 6. Officers elected: *President,* Dr. J. C. Moore; *Vice-President,* Dr. L. H. Redon; *Secretary-Treasurer,* Dr. Henry D. Brown.

**Obituary Notes.**—Dr. Orville Horwitz of Philadelphia, a graduate of the University of Pennsylvania in 1881 and of the Jefferson Medical College in 1883, a member of the American Medical Association, the Pennsylvania State and Philadelphia County Medical Societies, the American Surgical Association, the Philadelphia Academy of Surgery, the American Association of Genito-Urinary Surgeons, and the American Urological Association, and emeritus professor of genito-urinary surgery at the Jefferson Medical College, died at his home on January 28, aged 53 years.

Dr. James P. Tuttle of New York, emeritus professor of surgery in the Polyclinic Medical School and Hospital, died at his home, from diabetes, on January 31, aged 56 years. Dr. Tuttle was graduated from the University of Pennsylvania, Department of Medicine, in 1881, and was a member of the American Medical Association, the New York State and County Medical Societies, the American Proctological Society, the New York Academy of Medicine, and the Medical Reserve, U. S. A., consulting surgeon to the Manhattan State Hospital, and the Almshouse Hospital, and surgeon to the Polyclinic Hospital and St. Bartholomew's Dispensary.

Dr. Francis Hodgson Orme of Atlanta, Ga., a graduate of the New York University Medical College, in 1854, and formerly president of the American Institute of Homeopathy, died at his home on January 28, aged 78 years.

Dr. Mortimer H. Clarke of Auburndale, Mass., a graduate of the Boston University School of Medicine in 1888, and a member of the Massachusetts Homeopathic Medical Society and the Boston Homeopathic Society, died at his home from pneumonia after a short illness, on January 13, aged 52 years.

Dr. Nelson Asath Drake of Kansas City, Missouri, a graduate of Rush Medical College, Chicago, in 1868, a member of the American Medical Association, the National Association of Railway Surgeons, the British Medical Association, the Kansas, Iowa, and Missouri State Medical Associations, and the Jackson County Medical Society, being a charter member of the last and its oldest ex-president, a veteran of the Civil War, having spent four months in the famous Libby prison, and the founder and at one time editor of the *Kansas City Medical Index,* died at his home from Bright's disease on January 9, aged 70 years.

Dr. Edward K. Shirley of White Hall, Ill., a graduate of the Homeopathic Medical College of Missouri, St. Louis, in 1881, and a member of the Illinois State and Greene County Medical Societies, died as the result of an accident on January 19, aged 57 years.

Dr. Richard G. Johnson of Amsterdam, N. Y., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1883, a member of the New York State and Montgomery County Medical Societies and the Amsterdam Medical Society, and physician to the Amsterdam, City, and St. Mary's Hospitals, died at his home on January 20, aged 54 years.

Dr. Joseph R. Stuart of Houston, Texas, a graduate of the Jefferson Medical College, Philadelphia, in 1890, a member of the American Medical Association and of the Texas State and Harris County Medical Societies, and president of the Houston Infirmary, was instantly killed in an automobile accident on January 12, aged 44 years.

Dr. William Louis Rabe of Dwight, Ill., a graduate of the Rush Medical College, Chicago, in 1866, and a member of the Illinois State and Livingston County Medical Societies, and the American Medical Association, died at his home from pneumonia on January 15, aged 73 years.

Dr. John L. Lehman of Carmi, Ill., a graduate of the Indiana Eclectic Medical College, Indianapolis, in 1887, and a member of the Illinois State and White County Medical Societies, died at his home on January 17, aged 60 years.

Dr. Francis Nelson Braman of New London,

Conn., a graduate of the Bellevue Hospital Medical College, New York, in 1866, a member of the Connecticut State and New London County Medical Societies, chairman of the medical board of the New London Memorial Hospital, and formerly physician in charge of the Smith Memorial Home, and a member of the Board of Education, died on January 14, aged 76 years.

Dr. Eugene Elam Brown of Martinez, Cal., a graduate of the Hospital College of Medicine, Louisville, Ky., in 1882, and for many years physician of Contra Costa County, died at his home on January 10, aged 56 years.

Dr. J. W. Sorrells of Mansfield, Ark., a graduate of the Kentucky School of Medicine, Louisville, in 1876, died at his home recently from pneumonia, aged 49 years.

Dr. John Morrison of New York, a graduate of the Bellevue Hospital Medical College, New York, in 1892, was burned to death in a fire which destroyed his country home at Skillman, N. J., on January 22, aged 61 years.

Dr. Clinton Stevenson of New York, a graduate of the College of Physicians and Surgeons, New York, in 1889, a member of the New York State and County Medical Societies, the Association of Military Surgeons, the Greater New York Medical Society, and the Society of the Alumni of the New York Hospital, assistant ophthalmologist to St. John's Hospital, Long Island City, a surgeon major in the Eighth Coast Artillery, and medical inspector in the Department of Health, died at his home from pleurisy, on January 20, aged 47 years.

Dr. James Alexander Petrie, retired, of Phillipsburg, N. J., a graduate of the Department of Medicine, University of Pennsylvania, Philadelphia, in 1866, a veteran of the Civil War, died at his home on January 23, aged 70 years.

Dr. Sarah Josephine Wadsworth of Maplewood, N. J., a graduate of the New York Free Medical College for Women in 1876, died in St. Elizabeth's Hospital, New York, on January 20, aged 71 years.

Dr. Ezra Barnes Aldrich of Manchester, N. H., a graduate of the Harvard Medical School, Boston, in 1868, and a member of the New Hampshire State and Hillsboro County Medical Societies, died at his home on January 14, aged 72 years.

Dr. Reuben Fletcher Dearborn formerly of Lynn, Mass., a graduate of the New York University Medical College in 1874, died at the home of his daughter in London, Ont., on January 19, aged 62 years.

Dr. Charles Sturtevant of Hyde Park, Mass., a graduate of the Harvard Medical School, Boston, in 1862, a veteran of the Civil War, and associate medical examiner for Suffolk County, Mass., having held public office continuously for forty-two years, died at his home on January 19, aged 73 years.

Dr. John Winslow Chase of Dedham, Mass., a graduate of the Medical School of Maine, Portland, in 1867, a member of the Massachusetts State and Norfolk County Medical Societies, and for many years county physician and a member of the Board of Health, died at his home on January 19, aged 73 years.

Dr. William T. Black of Calais, Me., a graduate of the Pennsylvania Medical College, Gettysburg, in 1857, and a surgeon in the Union Army during the Civil War, died at his home from pneumonia, on January 13, aged 82 years.

# Correspondence.

## THE INFLATION OF STATISTICS.

To the Editor of Medical Record:

Sir:—I do not believe that a medical journal is the proper place for settling personal disputes, but the statements of Dr. Sheffield are so incorrect that I am compelled to reply. To prove my statements I enclose the records of the cases of the Vanderbilt Clinic and also a postal card which was sent to me acknowledging receipt of my manuscript. If you will kindly note the date on the records you will see that the sister had been under observation at the clinic since 1905, and the brother since 1911; the cases, therefore, were under observation by us for a long time before they were seen by Dr. Sheffield. If you will also note the date on the card you will see that I received it in October, whereas the doctor's article did not appear until November; how then could I have recognized the photographs when they were not published at the time when my article was in print?

When my article appeared Dr. Sheffield telephoned to me and asked me to send him a reprint; this I did. He in return sent me three reprints of three different articles, one of which was the paper in dispute. Not a word was said by him in this conversation in regard to the cases which he reported, and I did not know that he reported the same cases without a diagnosis until I had received his reprint. As I have never met Dr. Sheffield nor ever spoken to him except on the one occasion when he called me up, when was this imaginary apology of mine extended to him? How could I have apologized to him when I did not know the facts until I had received his reprint? Nor did he know that the cases which we reported correctly diagnosed were the same cases which he reported without a diagnosis, until he received my reprint.

In regard to the diagnosis, anyone who reads the article of Dr. Sheffield must see that he did not have the slightest idea of the correct diagnosis, for if he had, why would he have said "the presence of suppurative foci all seemed to warrant the assumption that anyloid degeneration was here dealt with," and "yet it showed nothing tangible to elucidate the diagnosis," and "disappointed in the diagnosis as well as treatment, I directed the mother to go with the child to the country."

In conclusion I beg to state that we had the cases under observation for a long time before Dr. Sheffield had seen them; that we correctly diagnosed and reported them before the doctor's article appeared, and that by his report the statistics of Splenomegaly (Gaucher) are neither inflated nor increased.

Mark S. Reuben, M.D.

New York.

## OUR LONDON LETTER.

(From Our Regular Correspondent.)

FIRST WEEK OF INSURANCE MEDICAL BENEFITS—TROPICAL MEDICINE—SIR RONALD ROSS'S LECTURE—MR. AUSTIN CHAMBERLAIN AND THE TROPICAL SCHOOLS.

London, January 17, 1913.

This is the first week in which the "Medical Benefits" of the Insurance Act take effect. On Monday maternity benefits became payable and already applications have been put in on behalf of insurance infants, the first of which has been presented by a can-

didate for the County Council with a gold medallion locket containing a portrait of the Chancellor of the Exchequer. On Wednesday the other benefits came into operation. It must be remembered, however, that insured persons are not entitled to medical attendance unless they have been insured throughout the last six months. As many delayed insurance the pressure on the panels has been less than was anticipated. A further modification of the six months' rule is now made; an official statement was issued last night to say that insured persons who are members of approved societies are entitled to medical benefit "no matter when they entered insurance or whether they have since been out of employment." Another sop for the clubs and proof of the determination to force administration through these "approved societies." In most districts the condition of the panels has been such that some sort of attendance may be reckoned on for the next three months, and when an act of Parliament has been working for that time there is more likelihood of amending than of repealing it.

The first official list of London panel practitioners was exposed at the post offices and other places on Tuesday, prefaced by an invitation to insured persons to apply to any one whose name appeared. Counting them gives a total of 1,949, so large as to provoke exclamation that there must be error. Looking further it appeared that men had put down their names for different districts and were inserted for all. The London Medical Committee at once scrutinized the list and the next day issued an estimate of only 738. Many names they found repeated in three to eight different lists and two of them appeared in ten. Conflicting statements have been issued each day since as to some withdrawing and others coming in. Last night the county of London official statement claimed only 780. It declared, too, that only three withdrawals had been received at the office. I don't know how to reconcile this with three times as many letters in the morning papers declaring the writers have resigned.

Meetings of all sorts have been held all the week. Last night there was a meeting called by insured persons to protest against being forced to take only panel doctors and demanding the right to choose any duly qualified practitioner. The free choice of doctor was again and again affirmed by Mr. Lloyd George to be most necessary and to form part of his bill. "Go to the doctor you believe in," he said in one speech, "that is the one for you and under this bill you have him—that is the government insurance bill." Words were inserted which to any ordinary reader convey that meaning. Now the bill has become an act his committees are trying to curtail this and drive every one to the panel men. I had a circular this week to inform me that the words did not mean what so many supposed, and stating that the intention of Parliament was choice among panel men only. Moreover, the committee would consider any particular case desiring to contract out, and if the applicant gave evidence of special reasons to satisfy them they would give permission—provided the doctor chosen promised to keep the same schedules as the panel men and provided he satisfied the committee that his treatment would not be inferior. No wonder men are exclaiming against lay control! Mr. Lloyd George must have known, as a lawyer, whether the words in the act expressed the free choice he guaranteed in his speeches. If by neglect or over-pressure he let them pass unwittingly he should protect his honor by ordering his officials to withdraw their circular and not to set up as interpreters of the intention of Parliament.

In the provinces, as I have previously informed you, the proportion who have joined the panels is larger. In the county of Middlesex, which is somewhat involved in the London fight, there are 386 on the list besides 61 men who since joining have resigned, but the committee state they have not been released from the contract. The ratio to insured persons will work out as 770 for each doctor.

To meet the expense incurred by its vigorous campaign the British Medical Association has been obliged to call up 20 per cent. of its guarantee fund.

To-day the representative meeting of the British Medical Association is being held. Practically it is to vote on the proposal to release men from the pledge they made in which there is sharp division of opinion. Some hold that the pledge was made to support the policy of the association and is still binding. Others say the policy has been changed by the leaders and so the pledge is abolished. It looks as if thousands signed the pledge without reading it and now discover in it a promise to support the association's policy. Some think they should do so although they disapprove the change. The question is being discussed and the vote is to be taken, but the result will not be known in time for this post.

Tropical medicine has occupied much attention this week. At the Royal Colonial Institute Mr. Arthur Chamberlain presided at a lecture by Sir Ronald Ross and in a brief, effective speech expressed the interest he felt in the subject and his pleasure in thinking our country had been a pioneer in the cause—thanks to men like Sir Patrick Manson and Sir Ronald Ross, who had spread abroad the fame and discoveries of our tropical schools. It is pleasant to find the son of the founder of these schools thus following in the steps of his illustrious father and "welcoming the opportunity" of hearing from the lips of one who had "played so large a part" in the progress already made and of the opportunities for further advance.

Sir Ronald Ross said that ten years ago he lectured before Mr. Joseph Chamberlain, at whose instance these schools had been started some years previously. To-day he could take a bolder flight. Then he could only record discoveries, now their practical application.

He felt strongly that tropical Africa remained uncivilized because tropical diseases prevailed. He instanced the effects of a number of these and stated their causes and the numerous, patient researches still being carried on toward their cure and immunity from them. Was not this knowledge, he asked, a gift to the race? The death rate had fallen wonderfully since 1903, while invaliding might be said to have "tumbled from the top to the bottom of the scale." This he held meant civilization for West Africa; it was a new, vast possession added to the empire and therefore a national obligation to mount the schools of tropical medicine that meant proper museums, extensive libraries, permanently employed teachers with the highest qualifications. In addition, ability among government medical men must be encouraged and investigation continued at every point. This had been done by enthusiasts practically unpaid, but it was time for the country to pay. The movement begun by Joseph Chamberlain had been continued by successive Colonial Secretaries, but with no expense worthy of a great country. He had himself been able to continue his

work, not by his countrymen but by foreigners. If change in this matter of payment were not made he could no longer advise young men to take up medical research. Britain gave throughout the empire less than £50,000 per annum for medical research which benefited 50,000,000 of whites, not to mention hundreds of millions of colored subjects—say one-tenth of a penny for each white. That was the gigantic contribution of a wealthy, grateful country to its medical investigators. Nowadays Parliament only paid itself—a quarter of a million pounds a year. Medical research could do much with that sum. As an example, measles killed 10,000 children a year and Britain spent some £200 or £300 a year on investigating it.

The chairman took up the question which Sir Ronald had thus opened and made a forcible appeal for the support of the tropical schools, which was the real object of the lecturer in his address. He had agreed to become chairman of a committee for raising a fund of £100,000. They had got £50 and he pleaded for the remainder.

At the Belgian Universal Exposition this year Great Britain will have an exhibition in illustrating in a popular way what is being done in relation to tropical diseases. A committee has been at work for some time and examples of the exhibits to be made have been shown at the Board of Trade. The committee is composed of representatives of our London and Liverpool schools, those of Khartoum and Cairo, the War Office, the Admiralty, and the India Office. Each of these undertakes the collection of certain specimens of insect pests, bacteria, microscopic and photographic illustrations, and so on. The London School of Tropical Medicine will show the work going on in connection with cholera, beri-beri, and elephantiasis, including any fresh information that may be obtained in the meantime concerning the outbreak of cholera among the troops engaged in the late war in the Balkans. The Liverpool school will illustrate the work on sleeping sickness and yellow fever on which it has done so much by its expeditions. The Admiralty will represent the work of the fleet surgeons on Maltese (undulant) fever. The War Office will show all that has been done on typhoid. The India Office takes charge of plague and there will be a special exhibit as to leprosy and other diseases of the East arranged by Dr. Andrew Balfour of the Egyptian service. As the chief object of this exhibition is to interest the public in order to instruct it on the necessity of prevention there will be specimens of mosquito-proof articles of clothing and furniture, with a model of a similarly protected house. A rat-proof house is also expected to find a place. The Liverpool school also intends to deal with foods which have been injured in preserving by being, for instance, deprived of phosphates, as husked rice. This school has given much attention to the question of preservation of food and will show examples of some which have been so injured as to be scarcely of any nutritive value.

5. An Anatomical Explanation of Many of the Cases of Weak or Painful Backs, as Well as of Many of the Leg Paralyses. J. E. Goldthwait.

2. **The Causation of Shock.**—E. H. Risley presents a summary of the evidence in regard to the causative factors in the complex condition of shock. This is stated to be a condition of lowered vital resistance produced by varying factors, such as fear, injury, or infection, of varying degrees. It is not possible to determine in a given case what physiological function is first disturbed or what the exact sequence of pathological changes may be, but shock does involve in its progress a disturbance of the respiratory center followed by a disturbance of the oxygen-carbon dioxide equilibrium, a lowering of body heat, and a depression of vasomotor tone resulting in a final paralysis or exhaustion of vasomotor activity, failure of respiration, cardiac failure, and death. Its treatment is based on a recognition of all of these factors. No one factor gives an adequate explanation of the phenomenon.

3. **Control of Ophthalmia Neonatorum.**—F. E. Cheney suggests the following measures that may be employed in the control of this disease: (1) The sending of a special notice to parents to prevent blindness in children, by every board of health in the State upon the receipt of birth notices. (2) A law requiring all cases of ophthalmia neonatorum to be placed under the care of an oculist or at least the supervision of an oculist within a certain time after the symptoms of the disease are first noticed. (3) Printed matter, as to the recognition of the disease, immediate care and protection of the eyes, laws relating to the disease, etc., should be sent to all doctors, nurses, and midwives, at regular and frequent intervals, and over a long period of time. (4) While the use of a 1 per cent. solution of nitrate of silver cannot be regarded as objectionable, a more universal prophylaxis against this disease would probably result if the use of a non-irritating silver preparation were more generally recommended and encouraged.

4. **Typhus Fever at the Massachusetts General Hospital.**—R. J. Lee notes that in the past ten years typhus fever in a mild and sporadic form has constantly been present in Boston and its vicinity as seen by the records of the Massachusetts General Hospital. It occurs, according to the Massachusetts General Hospital statistics, in about the ratio of one case of typhus fever to 47 cases of typhoid fever. As the diagnosis has to be made upon clinical signs only, it is possible that there are other cases in this series which cannot now be definitely diagnosticated. There occurred in the hospital series another group of cases which roughly simulated typhus fever in everything but the presence of the rash, which cases cannot now be classified. The clinical course and laboratory findings in typhus fever are so distinctive that there is little trouble in making the diagnosis in typical cases. This study throws no light upon the epidemiology of typhus fever, except that the occurence of the disease in persons of Russian nativity strongly suggests that the disease was originally imported from Russia. This study also emphasizes the importance of blood cultures, inasmuch as there were cases of typhoid fever with a negative Widal in which the positive diagnosis was made only by blood cultures. Moreover, the diagnosis of paratyphoid fever in this series was made possible by blood cultures alone in the majority of instances.

1. **Tuberculosis and Schools.**—By S. A. Knopf. (See MEDICAL RECORD, September 28, 1912, page 577.)

2. **Sex Ethics.**—W. B. Konkle points out that the march of morals is slow, and that sexual morality constitutes no exception to this rule. It cannot be predicted when love will extinguish lust, and solicitude for, and devotion to the interests of posterity will supplant tyrannous impulse toward self gratification. It is known, however, that many fields of labor are involved in the working out of the problem, and that much must be done in each of them. The eugenist must look to the improvement of the human stock. The pediatrist must see that childhood and youth are not impaired or vitiated. The andrologist must be not simply a specialist in venereal diseases—he must do for man what the gynecologist is doing for woman. The sanitarian must make earth and its abodes harmless and healthful. The sociologist must get things so adjusted that there will be peace and content and concord in the human hive. The theologian has a most important part to play. He must keep God in the thought of men as the One who dictates duty and creates responsibility.

3. **Pertussis Vaccine.**—G. D. Scott reports the results that he has obtained after eighteen months' work with pertussis vaccine. His patients now number seventeen. Pertussis vaccine is not a panacea in all whooping cough cases. In a few cases in which the disease was not cured the symptoms were distinctly mollified. The number of attacks became less, their severity was diminished, cyanosis was less marked, or vomiting during the paroxysms disappeared. The children slept better and the attacks at night became less. In not one of the author's cases was there any reaction from the vaccine. Experience seems to confirm that stronger doses of vaccine should be given in the early stages of the disease; also that infants require fewer and stronger doses than do older children. The younger the infant the quicker the cure. The author now begins with forty million bacteria, even to an infant, and gives another dose in proportion to the effects following the last dose. If much benefit arises he prolongs the intervals, if little or no benefit he shortens them. Many of the cases improved after one dose. An infant of five months was cured, others were improved after the second, third, or fourth. A dose of forty million given in severe cases at short intervals, is believed to be better than larger single doses.

4. **Conservative Treatment of Cancer.**—R. H. Boggs believes that a more conservative treatment of malignant growths should be practised in order that one may secure more positive results in curable cases and effect greater palliation in hopeless cases. The degree and location of malignancy should determine the treatment. Good results follow early operations if the tumor is favorably situated. Postoperative Röntgen treatment, even in these early operations, decreases recurrences. Some unfavorable cases can be made more favorable for operation by anteoperative treatment. Hopeless cases which have not been operated upon derive more benefit when compared with hopeless recurrent cases. With many the Röntgen ray is superseding all other methods, even excision radically performed, in the treatment of epithelioma, unless it involves mucous membrane.

2. **Contracture of the Neck of the Bladder.**—C. H. Chetwood states that there may occur circular sphincteric and prostatic stenoses with partial or complete urinary retention. Contracture of the neck of the bladder may occur in young or old, with or without prostatic enlargement, may be confined to the internal sphincter or encroach on the prostatic urethra, and is amenable to surgical relief. There are reports in the literature of numerous cases of vesical atony attributed to arteriosclerosis, circulatory disturbances, senile changes, degeneration of bladder muscle, local nervous diseases and infection. The author believes a prolonged inflammation or congestion may have antedated some of these causes. He reports a case in which the removal of the sphincteric orifice and prostatic urethra at autopsy showed the urethral outlet vigorously contracted, and histological examination showed a pronounced inflammatory process as its basis. The reported cases of bladder atony, the causes of which are neither neurological nor mechanical so far as ascertained, are, according to the author's view, sometimes of specific origin, and he mentions a case in which specific treatment relieved the condition. The mystery surrounding some of the cases might possibly be cleared up if one had a better knowledge of the functional mechanism of the vesical prostatic outlet than one can gain by cystoscopic observation. A slight valvular abnormality might account for some while others may be due to some abnormality in the central nervous system. In the mechanical cases surgery is the only relief. The author's method is to use the galvanocautery through a small perineal cut of the vesical constriction on one or both sides, according to the case. He considers this very much better than any intravesical operation.

4. **Impermeable Stricture of Urethra.**—J. B. Deaver notes that the membranous urethra is the seat of inflammatory stricture, though ordinarily the bulbous urethra is involved in deep stricture. He reviews the methods of attacking impermeable stricture and condemns the blind perineal section. Incision exposing the urethra anterior to the stricture, which is the method most used, has the disadvantage that one is often unable to pass any instrument through the exposed strictured area and one must either make a perineal dissection or carefully dissect backward to the dilated portion of the urethra until the stricture is laid open. Young's operation consists in incising the urethra through the tissue of the apex of the prostate after its exposure by the perineal method. This has undoubted advantages, being carried out on definite and anatomical lines and is the simplest procedure of all. Primary or secondary suprapubic incision into the bladder as a preliminary to urethrotomy behind the stricture, is also condemned. As regards the treatment of the stricture area after it has been exposed, the older teaching was to drain and dilate. The more modern methods of excising the entire area and reuniting the severed urethra over a catheter or supplying the excised tissue from other parts, is too time-consuming to be used in many cases. There is no reason, however, why one should not remove as much as possible of the dense organized scar tissue. It is a help to nature's reparative powers and there is less tendency to new contracture than with mere incision and drainage. Another point emphasized is that a perineal drain should be left after a perineal operation. It is the author's plan, after

establishing a passageway, having excised all the dense scar tissue and having placed a catheter inside the bladder closed over with what tissue he can find in layers, to always bring the catheter out of the urethra anterior to the point of stricture and fasten it to the anterior angle of the skin incision in the perineum. Whether another catheter is to be placed in the anterior penile urethra and brought out through the same wound is a matter for the judgment of the surgeon. The author has had good results both with and without this addition.

5. **Section of Anterolateral Column.**—E. Beer concludes that, surgically considered, the operation of cutting the anterolateral column without doing serious damage to the rest of the spinal cord is perfectly feasible and not difficult. Therapeutically considered, the almost complete freedom from pain produced by this surgical intervention met the indications presented in the case reported by the author, and in many other sufferers a similar intervention would probably give similar relief. Physiologically considered, section (complete?) of the anterolateral column produces (a) a loss of pain sense on the opposite side of the body; (b) a disturbance in thermal sense which suggests that the fibers for heat and cold are disassociated in the cord; (c) slight disturbance of deep pressure sense and slightest disturbance in touch sense, both being impaired without producing any disturbance of the sense of position.

7. **A Possible Factor in the Causation of Pellagra.**—A. H. Jennings and W. V. King suggest that the cosmopolitan stable-fly (*Stomoxys calcitrans*) may be an important factor in the transmission of pellagra. It has practically uniform habits throughout its range and it is abundant in most places, sometimes entering the dwellings in considerable numbers, though it prefers to attack domestic animals, but it readily bites man and it takes its meals from multiple sources, passing from one animal to another. The author's hope is that attention may be directed to the fly as regards its relation to pellagra. Should a causative organism be shown to exist which is a bacterium rather than a protozoon, and should this organism invade the body through the mouth or skin, the common house fly might be strongly suspected as a carrier. The authors also admit that the communication of pellagra in a purely mechanical manner by biting insects is a possibility, and if shown to exist would radically change our ideas as to the species which may be involved.

8. **Malignant Renal Tumors.**—W. F. Braasch emphasizes the importance of immediately ascertaining the source of every hematuria. Of the fifty-three patients operated on for malignant renal tumor who had a definite history of hematuria, but eighteen, or 34 per cent., had been advised to be examined for its source. Hematuria, particularly when so well marked as to color the urine, is always to be considered a sign of some grave condition in the urinary tract. In fact, it would be conservative to regard every case of hematuria as the result of a malignant process until it can be definitely proved to be otherwise. Renal tumor may lie dormant or grow insidiously over a period of years and by the time that hematuria, tumor or pain calls attention to its existence, it should receive immediate surgical attention.

1. **The Etiology of Endemic Goiter.**—R. McCarrison, who has had an extensive experience in the study of endemic goiter in India, notes that two facts emerge from the study of the geographical distribution of this disease. The first is the very marked association of goiter with regions of high mountains; the second, the comparative limitation of the disease to temperate and subtropical zones. There appears to be a family predisposition to the disease. It is found in the large majority of the cases in laborers and miners—in those whose occupation brings them into contact with the soil. The endemic of goiter prevails with different degrees of intensity in different countries and in different parts of the same country. Goiter has made its appearance in many places in which it was formerly unknown. The disease exhibits a distinct seasonal prevalence. In Gilgit and Chitral new cases of goiter arise and enlargements of pre-existing goiter take place during the spring and autumn months, that is to say, during the months of moderate heat. Epidemics of goiter occur in endemic centers, in the neighborhood of such centers, or in localities where the disease has previously been prevalent. It is the author's experience that goiter generally develops in susceptible individuals in a period varying from six weeks to three months after their arrival in a goiterous locality. It is commonly believed that in all endemic localities, not only man but animals also suffer from goiter. Goiter is more common in females than in males, and is considerably more common in children than is generally supposed. With the possible exception of rats, animals do not readily acquire the disease under experimental conditions. Water is capable of conveying in some manner, as yet incompletely determined, the toxic agent of endemic goiter.

4. **Autoinoculation Treatment of Pelvic Inflammation.**—H. Chapple has applied this method in cases of bilateral chronic salpingo-oöphoritis with a very definite history of gonococcal infection. He notes that it is now generally accepted that an increased blood supply to an infected area causes the liberation of an increased quantity of toxins into the general circulation, thus producing an autoinoculation with the products of the actual offending organisms. So by raising the local temperature of the pelvis sufficiently for a definite length of time an increased blood supply to the pelvic organs is induced, and an autoinoculation capable of sufficiently accurate control is effected. The difficulty of isolating the offending organisms is thus overcome. The best results are obtained by regulating the dose both as regards quantity and time of introduction, the aim being to give the second dose when the negative phase produced by the first is over and the positive phase has been definitely entered upon. By this means one can raise the patient's index to the offending organisms and markedly increase her ability to deal with them and their products. Should one be dealing with a case in which the trouble is dependent on an inflammatory mass due to an organism now dead, the pelvic congestion is still of great value, in that the increased vascularity assists in the absorption of the inflammatory products. These processes go on side by side. The desired pelvic congestion is easily produced by the heat emanated from several powerful electric lamps, which are suspended from a suitable cradle, which surrounds the patient's pelvis. It is customary in the use of heat baths in these cases to cover the whole of the patient's trunk and limbs. At first the author adopted this method, but this is obviously not a rational procedure when the object is to produce a definite congestion localized to the pelvis. The cradle should surround the pelvis only,

and the rest of the body and limbs be left uncovered. With the apparatus so arranged the temperature is raised gradually to the maximum the patient can bear, and after a few days a temperature of 180° F. or thereabouts will be reached, and the patient is submitted to this for half an hour at least. When the whole of the body was covered the mouth temperature was found to be raised, and the process was an exhausting one, but with the heat applied only to the pelvis it was usually borne with ease. A maximum thermometer placed in the vagina recorded, even when the bath temperature reached 190° F., an average rise of only 0.5°. This seemed to be a great waste of heat to produce so slight an effect. These observations were also of interest as showing what a slight effect on the deep pelvic structures must be in reality produced by an ordinary hip bath or so-called hot vaginal douche. However, by introducing into the vagina a suitable Fergusson's speculum with its upper end in the posterior fornix and consequently lying almost in contact with the inflammatory area, and its lower end in direct communication with the bath, it is possible to raise the vaginal temperature very considerably and also the actual temperature of the pelvic structures in the neighborhood of the pouch of Douglas.

**8. Thromboangeitis Obliterans of Buerger.** — F. Parkes Weber in reporting a case of this condition states that the disease has been chiefly or almost exclusively observed in male Jews between thirty and fifty-two years of age who have emigrated from Russia. Syphilis apparently plays no essential part in the etiology of such cases, and the real cause of the vascular disease remains unknown, though tobacco smoking may be suspected of being a contributory factor. Most of the patients have been free cigarette smokers, and many of them have been employed in cigarette factories, where they could obtain cigarettes without paying for them. The characteristic symptoms of the disease, as illustrated by the author's case, are: (1) Redness or cyanosis of the foot when it is allowed to rest in a dependent position; (2) pallor of the foot on movement of the ankle-joint; (3) intermittent claudication, with feeling of cramp or pain in the muscles of the calf or instep on walking for a few minutes. (Walton and Paul have termed this "angina cruris" when, as in most cases, one of the lower extremities is the part affected); and (4) absence of pulsation in the arteries of the foot, notably in the dorsalis pedis artery.

**1. Pericolitis.**—T. Carwardine notes that this condition has its simplest manifestation in the local peritonitis accompanying the firm impaction of a fecal mass in the colon. In lesions of the mucous membrane of the colon causing infection through the lymphatics the adjoining mesentery becomes thickened and shortened from chronic inflammation, a feature met with opposite the diseased area in chronic appendicitis, which causes kinking of the appendix at its middle or proximal part. Wandering kidney sometimes causes colitis. This is primarily mechanical, from local irritation, from displacement and distention of the ascending colon, and from the strain on the colic vessels acting more readily upon the veins than on the arteries, and so inducing passive congestion. In addition, the colitis causes infective inflammation of the pericolic tissues. Thus a vicious circle is induced, mechanical on the one hand, infective on the other; the cecum and ascending colon being in lymphatic connection with the right kidney, so that bacteria and toxins can pass from the colon to the kidney. The association of membranous pericolitis, with symptoms of chronic appendicitis has been described by L. S. Pilcher. The bands may be thin and veil-like, membranous, or as firm sheets of fibrous tissue binding down the cecum and appendix. They tend to restrict peristalsis and to angulate the colon and appendix. Lane has described similar adhesions between the outer wall of the colon and the parietes in connection with chronic constipation, and regards them as hypertrophy of the membranous anchors of the bowel, compensating for the strain of prolonged ptosis but also interfering with peristalsis. The symptoms of pericolic membranes have a great similarity, and resemble closely those of chronic appendicitis. Discomfort and pain are complained of in the right iliac region, with tenderness on deep pressure. These vary with diet and exercise, and colicky cramps occur which may be felt and even seen. Cecal constipation is caused by the defective peristalsis and mechanical impediment, and pain is caused by muscular spasm. This fecal stasis, in which absorption is normally active, causes symptoms of autointoxication. The pain is often referred to the stomach, and secondary digestive disturbances are common. In the later stages of actinomycosis of the appendix, which is not at all uncommon, the pericolic tissues become infiltrated and sinuses form in the loin. Inflammation of the gall bladder, leading to localized peritonitis in its neighborhood, is a common cause of pericolitis in the hepatic region, and is invariable in severe or long-standing cases.

**2. Drainage of the Abdomen.**—A. E. Barker believes that abdominal drainage has been employed too much as a routine procedure particularly in cases of inflamed appendices, and that more discrimination is desirable. After the removal of the inflamed organ and the septic products around it as far as possible by careful mopping, one might perhaps with advantage in some cases stitch up the abdominal opening after cleaning its edges, and obtain primary union with all its advantages. Here, of course, some traces of the septic matter would be left behind within the abdomen; but this can be disposed of by the defensive powers of the peritoneum. So far as can be seen from clinical and experimental observation, a very considerable amount of septic matter is tolerated by the peritoneal surfaces, and can be prevented by them from doing irremediable injury when not in too great amount or overpoweringly virulent. In many cases of perforated gastric ulcer drainage is of no use if not actually injurious. If on opening the abdomen a pyosalpinx with localized peritonitis is found, there need be less hesitation. Here the immediate closure of the wound may be done in the large majority of cases. The pus from pyosalpinx is sterile in about 50 per cent. of ordinary cases. In this group there is no special reason for drainage if oozing from adhesions can be quite controlled. But in the other half of the cases the virulence of the bacteria mitigated by long residence in the body is low, as indicated by the plastic exudation and the absence of inflamed and paretic intestines, and a carefully sutured wound will heal *per primam* in the majority of cases in spite of the pus. Again, in another class of lesions the same question has to be considered. The author alludes to gangrene of the gut from internal strangulation. Here, except where there has been perforation and fecal extravasation, drainage should be avoided after removal of the damaged portion. The plastic processes ap-

pear to be more perfect without a drain, which may prevent the apposition of healthy structures around the line of suture.

6. **Rectal Feeding.**—N. Mutch and J. H. Ryffel note that the rationale of the use of nutrient rectal enemata rests upon the assumption that nutrient maerials can be absorbed by the colon and are metabolized in a normal manner when absorbed. When given in this way saline solution is undoubtedly useful as a source of water. Dextrose solution is fairly well absorbed, but starch and fat are probably of no value. The utility of protein is doubtful. Langdon Brown found no increase in urinary nitrogen as a result of giving partly predigested protein by the rectum, and concluded that earlier observations, showing that as much as 50 per cent. of the protein given might be absorbed, were largely fallacious owing to the notorious difficulty of washing out the colon completely. In these experiments 10 per cent. dextrose was employed in order to obtain as large an absorption of dextrose as possible, but for general use a 6 per cent. solution in tap water, which is isotonic with blood, would be found more convenient as it is less irritating; 15 ounces or more of this solution given four times a day is frequently well retained by an adult, if the rectum is thoroughly washed out once a day with saline solution. It is more useful than saline solution in that the 100 grams or more of dextrose which is thus daily supplied to the body causes a diminution of nitrogenous waste, and the substance employed to render the solution isotonic is oxidized in the body, so that isotonic dextrose solution is more efficient as a source of water than an equal volume of isotonic salt solution.

7. **Renal Calculus in Childhood.**—R. Ollerenshaw emphasizes the importance of being on the lookout for renal calculi, which are probably much more common during childhood than is generally supposed. In cases of abdominal, spinal, hip-joint, or lumbar pain in which the signs and symptoms are not clear, the urine should be carefully tested and a microscopic examination made. The kidney area should be closely examined and a skiagram taken of the whole urinary tract. If possible a cystoscopic examination should also be made. If no sepsis has occurred, the prognosis is excellent. Postoperative shock is the only real danger. When sepsis is present a fistula may persist—this happened in Morris' case and required nephrectomy to remedy it. Palliative treatment by alkalies and other solvents may be effective when mere sandy particles are present, but when a calculus exists of size sufficient to be shown on an *x*-ray plate, it is quite certain that nothing short of operation will remove it. It must also be borne in mind that the sooner the operation is undertaken the better the condition of the kidneys, and therefore the better the chances of success.

*January* 13, 1913.

**Enterogenous Intoxication; Enterogenous Polyneuritis.**—Von Noorden states that the word autointoxication is greatly abused. It was first applied to the terminal stages of diabetes, uremia, cholemia—conditions which were quite definite. Then Bouchard introduced his ingenious conception which so broadened the idea of autointoxication as to make it obscure and vague. For this result Bouchard was in nowise at fault, but those who came after him. Some years afterward a relatively new conception was developed in connection with the ductless glands (thyreotoxicoses, etc.). A distinction must of course be made between endogenous and oxogenous intoxication, the latter practically the same as the so-called "intestinal autointoxication." Since the latter can hardly in any sense be endogenous,, it is best to speak of it as "enterogenic intoxication." There is, no doubt, a border line, *i.e.* there may be poisons manufactured directly in the gastroenteric wall, but of these we know at present nothing. In regard to enterogenous intoxication we know much. The ordinary clearage products of tryptic digestion comprise substances essentially toxic and we do not understand why we are not more frequently poisoned by them. Further the bacterial intestinal flora induce the formation of known toxic substances from the protein of the diet. In recent times there has been much effort to suppress or minimize the formation of these substances —notably by Metschnikoff, but the fact remains that the great meat-eating races which have dominated the world have always had this problem to deal with and show no evidences of deterioration in any respect. A study of works like that of Combe on autointoxication shows for the most part a lack of exactitude in results. We need to be shown just what these poisons are, and what results they are able specifically to produce. The conclusions drawn from these books seem impracticable—such as sparing the resistance of the intestine. The author would prefer to fortify it, of the two courses. Coming now to actual cases of enterogenous poisoning the author gives the following picture of disease: Constipation with habit of taking purgatives (the bowels sometimes move daily of themselves); accumulation of fecal matter in the sigmoid; hyperacidity, due apparently to the colonic atony; tenderness over sigmoid. When instead of constipation we find diarrhea this in nowise changes the nature, for the diarrhea is purely a reflex from the irritation of the feces. It may assume the form of mucous colic. The proctoscope in such cases shows the real nature of the condition. The chief somatic consequence of this condition is apparent in the absorption of some neurotropic substance. Neuralgiform pains appear here and there and in some instances the affected nerves are sensitive to pressure. The same pains may seem to affect muscles and joints and in all cases are fugacious in quality. The author states that as far as the neuralgiform pains are involved these connote a mild neuritis of a selective character. Cardiac neuroses, vacomotor neuroses, may proceed from the same source. In these cases indicanuria is usually marked, serving as an indicator. A toxin has been extracted from the feces which exerts an irritant (vagotonic) action on the vagus. This toxin is doubtless bacteriogenic and flourishes because of some special nutrient substance. Its determination will necessitate prolonged research. We naturally think of some paratyphus-like germ. In this type of enterogenous intoxication we frequently see a temperature rise which vanishes promptly when the bowel has been disintoxicated. Treatment of this affection must materially be protracted, and two or three weeks will elapse before the condition of diet can be decided. We must not confuse these subjects with neurasthenics and arthritics. While no general scheme of treatment can be given offhand, most cases do best on a diet of milk, sour milk, Kefir, etc. Others, however, become worse on this regimen, and improve on a diet of cereals and even sugar, and there are even some who must have mostly animal food.

*January* 18, 1913

**Sources of Persistent Increased Blood-Pressure.**—Schlayer states that in many diseased states the blood-pressure is persistently elevated: this we have learned through sphygmomanometry. We may cite here bronchial asthma, neuropathy, tabes (crises) in which the interval of increased pressure is relatively short. But there are other conditions in which there is no tendency of the pressure to become lowered and in which a pressure of 250-260 Hg may persist indefinitely. The first element to be isolated of causal significance was kidney disease, while next in order came aortic insufficiency. Graves' disease

was third in order, and in this affection the heart is, of course, directly implicated. An attempt was made to uncover some renal or arteriosclerotic component but this was found to be not worth while. A school of opinion also asserted itself to the effect that arteriosclerosis alone never causes high blood-pressure. Beginning in a measure anew the opinion soon acquired sway that a blood-pressure up to 160-170 invariably meant a renal component. Quite recently the very opposite opinion has gained ground, based on the declaration that many subjects who exhibited for years high blood-pressure showed on autopsy no renal lesion whatever. Evidently the entire subject demanded a new, unprejudiced investigation. Such a one was undertaken by Fischer. Of a large material with permanent pressure above 140 over 60 per cent. showed clinical evidence of nephritis while in about 15 per cent. there was a suspicion of such a condition. In at least 23 per cent. the kidneys could be excluded outright. If we select those only who have a pressure of 160.80 per cent. pointed surely to kidney disease, 16 per cent. probably to the latter and but 3.6 per cent. could be pronounced free from renal lesion. The author in his own studies found evidence of renal lesion (by autopsy) in every individual case of increased pressure, but the patients studied (Suabians) are extremely prone to kidney disease. The practical significance in these cases is hard to determine. We know that protracted hypertension may vanish in time, even in cases of renal disease. The exact relationship between renal lesions and arterial reaction is still unsolved.

**Causation of Infantile Paralysis.**—Josefson has investigated this subject in Sweden, one of the countries most ravaged by the Heine-Medin disease. His results are in agreement with those obtained in the United States and elsewhere. Numerous experiments were made to test all the possibilities announced from time to time, and the order of research does not vary essentially from that established in other localities. Animal inoculation from suspected substances was practiced. While flies *per se* could not be implicated in this research, the dead matter upon which they feed could be accused with probability. "Handkerchief extracts" of suspected carriers were freely tested and were readily found to convey the disease. The dust of rooms of victims was also found to be infectious. It seems undoubted that the parasite may flourish outside the body on dead albuminous matter for a variable period. It may, of course, reach the food and exist in it, but researches in this direction have not yet been undertaken.

*December 19, 1912.*

**"Thirst Cures" in Chronic Bronchial Affections.**—Singer refers to the customary management of bronchiectasis, bronchoblenorrhea, putrid bronchitis, bronchial asthma, etc., the aim being to secure an expectorant effect. Inhalations, drink cures, climatic and hydriatic procedures, balsamics, posture cures, compression cures have been used with more or less success. The opposite idea of a dry cure has been but little employed, although tested to some extent in collections of fluid, obesity, etc. It is open to some grave objections, at least in theory; and some of those who have used it extensively warn against carrying it to extremes. Naturally it coincides with experimentally induced states of thirst. It is well in thirst cures to let the patient eat what he wants in quantity as well as quality. Further, he should not cut off his water supply suddenly. A dry cure may be carried out as follows: For three days take fluids to extent of 200-400 ccm. in the form of water, milk and soup, or entirely as white wine. If extreme thirst develop use oranges or lemons. The fourth day may be a drink day in which as high as 2000 ccm. may be drunk. Thirst may be artificially treated by a few drops of anesthesin or eucain solution, as in exclusive rectal feeding. The conclusions as to the efficiency of dry cures in chronic bronchial affections are as follows: In a modified form in which dry days are the exception instead of drinking days, the amount of sputum is much diminished, not only for the time being but to a certain extent permanently. This dry treatment may be enhanced by adding sweating cures, electric light baths and atropin or alternating them. The dry treatment is also well adapted to antagonize the spasmophilic state in bronchial asthma.

**Tuberculous Etiology of Menstrual Disturbances.**—Hollos speaks of the long-known fact that incipient tuberculosis can suppress the menses to a greater or less extent. This relationship is variously explained, as by anemic suppression. After five years of study the author announces that the amenorrhea results directly from tuberculosis toxins formed somewhere in the organism. They coexist with other toxigenic phenomena. While the best-known type is protracted amenorrhea, great irregularity is common in the intervals and in the length of the periods themselves. Extremely common is dysmenorrhea (painful hemorrhage). Numerous other symptoms cited by the author are such as are commonly associated with suppression. The author has been able to provoke dysmenorrhea by the injection of tuberculin. The prognosis in these cases seems better (?) than in tuberculous women who present no menstrual difficulty. In fact, Hollos thinks, the subjects with menstrual troubles seem to have been immunized to some extent.

**The HCl Treatment of Pernicious Anemia.**—Croftan of Chicago refers to an earlier publication on this subject. He believes that HCl treatment is pure substitute therapy, as these patients suffer with achylia. He administers 15 drops of the strong acid after each meal. Three remarkable cases are given in full. Although cured of the anemia the achylia may persist, so that HCl must be taken off and on. In all he has notes of 14 cases with notable improvement. Colleagues have also reported favorably on the method, but a number of the cases treated were not pernicious anemia. In Europe Hess has published good results from HCl and high protein feeding.

---

**The Intolerance of Children to Morphine.**—A. Ravenna reports the case of a 17-month-old infant that received for its paroxysms of pertussis a subcutaneous injection of morphine. As the result of an error in the preparation of the solution, the latter contained 0.01 gram instead of 0.001 gram as was intended. The injection was followed by severe collapse with subnormal temperature, coma and extreme miosis, from all of which the infant slowly recovered in response to stimulation. This case indicates that although the child is quite susceptible to the influence of morphine, one need not be too anxious in administering this drug to children.—*Rivista di Clinica Pediatria.*

**Congenital Syphilis and Mental Disease.**—H. R. Dean classifies the cases in which congenital syphilis is the cause of disease of the nervous system into three groups: (1) The first group includes infants who are born with marked evidence of syphilis. In these cases the brain, together with other organs of the body, is the seat of marked change. These children as a rule die within a short time of their birth. (2) This group includes children who appear to be healthy at birth but which develop mental defects at the time of the second dentition or at puberty. To this group belong the cases of juvenile general paralysis. (3) In this group may be placed those cases of mental deficiency, imbecility and idiocy in many of which the Wassermann reaction constitutes the sole evidence of a syphilitic orgin.—*British Journal of Children's Diseases.*

## Insurance Medicine.

**Albuminuria in Life Insurance.**—In a paper read before the New South Wales Branch of the British Medical Association, Dr. C. MacLaurin tells of the methods employed by the Mutual Life and Citizens' Company of Sydney to decide the acceptance of applicants who have albuminuria. A distinction is made in those cases which show albumin in the urine before and after the age of thirty. Those over thirty the writer considers poor risks and but rarely accepts; of those under thirty he carefully considers both family and personal history and general physical condition before making a decision. A history of either scarlet fever, diphtheria, nephritis, cardiac lesion, or poor physique in these albuminurics is sufficient ground for exclusion. Of the great number remaining, however, he finds the majority fit for insurance. Much judgment must be displayed in the selection of these cases; often these young albuminurics are government workers, and insurance is required before they enter the civil service. Also, the interests of the company must be safeguarded.

All substandard lives are classified as immediate, increasing, and decreasing risks. Immediate risks cover those in whom, organic disease being present, death is apt to occur shortly after insurance. Decreasing risks cover those with a faulty family history, for instance, tuberculosis, and the applicant himself is physically under normal, but not tuberculous. It is known that the longer he lives the less risk there is of tuberculosis developing. Increasing risks cover those who may be expected to reach middle life without any special physical failing, but who degenerate earlier than the average healthy individual; these are typified by men with certain heart lesions, chronic asthma, etc. Under this head are classed the young albuminurics; for while there is sufficient evidence that they reach middle life in safety, little is known of their subsequent progress. So this is considered the fairest and safest way to deal with them. A special form of endowment is adapted for these increasing risks and has proved very popular among these young albuminurics, who otherwise might be refused assurance. A little higher premium is asked and risks are so calculated that, while the office is protected, the applicant is decidedly benefited. In cases where there is a possibility that real organic disease, though latent, may develop, a three or four years' condition is imposed. By these means many who would be refused insurance are accepted and on very favorable terms. The ultimate result, as yet, is not known, but the evidence tends to show that the result will be favorable to both sides.—*Australasian Medical Gazette*, November, 1912.

**Statistics of Rated-up Lives.**—In his presidential address before the Life Assurance Medical Officers' Association, at the annual meeting, held in London, on February 14, 1912, Dr. F. de Haviland Hall drew attention to the statistics of the rated-up lives of the Rock Life Assurance Company. He was distinctly of the opinion that there exists a tuberculous diathesis; in other words, some individuals are born with slight powers of resistance against the tubercle bacillus, and without exception become ready victims if they are exposed to infection. With regard to rating for gout, judging from the experience of the Rock Company, Hall thought they should emphasize the importance of a very careful examination of applicants with a gouty history, especially as regards the condition of the cardiovascular system. Referring to syphilis, he expressed the opinion that possibly in the future it might be found that applicants who gave a negative reaction to the Wassermann test could be taken without loading. Want of vigor and general condition of the applicant was passed in review and Hall deemed that the statistics of the Rock Company justified the conclusion that applicants of this kind should be regarded with suspicion. He thought that the figures available favored the view that the experienced medical practitioner was able to recognize from the appearance of the individual, apart from any definite physical signs, that he had an expectation of life less than his age. He said that he was afraid that the tendency of the physician of to-day was to depend too much upon the results of the pathological and bacteriological laboratories, and that he was neglecting the thorough inspection of the patient which was practised by the great physicians of the past generation. Hall was convinced that individuals, who were much over-weight, were very unsatisfactory lives. It was pointed out that in only three instances was an addition imposed on account of occupation, and in all three the reason for the addition was the fact that the applicant was a licensed liquor dealer. In conclusion, attention was drawn to the fact that in rating up damaged lives more definite figures were needed. America had set an excellent example in this direction, and he trusted that Great Britain, which was the pioneer of life assurance, would wake up and assist in this important task.

**Apoplexy Due to Accident.**—A case is related in which on the testimony of a fellow employee an individual was seen to have been suddenly paralyzed during his regular hours of labor; or, more exactly, his duties having just been completed he was about to dress to go home. He had just assisted in moving a piece of furniture from the factory to the storehouse. The weight was about 200 lbs, and it was only moved on the level. The victim's trade union refused to recognize the stroke as having been due to the occupation. The exertion made beforehand was strictly within the limits of his regular activities. The plaintiff, backed by the family physician, brought action. The court sought to determine whether the attack had been one of ordinary apoplexy or an apoplectiform attack in connection with general paralysis. The latter could be readily excluded. As a case of genuine apoplexy the supposition was that if the blood vessels had been abnormally brittle from calcareous degeneration, the elevation of blood pressure in lifting the furniture might cause a rupture of an artery and hemorrhage. The court sustained the claim of the plaintiff, whereupon the union appealed the case but by reason of another expert opinion, withdrew the appeal and paid the full annual indemnity. Later, the patient suffered a second stroke and finally a third fatal one. In neither of these was there any apparent element of exciting cause. It was thereupon finally decided that the first stroke had no necessary connection with the occupation. The union was released from all obligations under litigation. The fact was apparent that when the patient's physician first promptly called the case an accident of occupation he paved the way for all the subsequent litigation.—*Zeitschrift für Versicherungsmedizin*, 1912, V. Heft 9.

# Book Reviews.

Sprue. Its Diagnosis and Treatment. By Charles Begg, M.B., C.M., Edinburgh. Formerly Medical Officer Chinese Imperial Maritime Customs, and H.B.M., Medical Officer, Hankow, China. Illustrated. Price $2 net. New York: William Wood & Company, 1912.

Sprue is a disease the importance of which is hardly fully recognized. It is the cause of a considerable amount of sickness and disablement in the Far East. Furthermore, its geographical distribution is wider than is generally imagined. Dr. Begg has had a long experience of the malady in the Far East and consequently his conclusions thereon are valuable. As for its etiology he holds that sprue is a microbial infection of the bowel of unknown origin. With regard to treatment the author is of the opinion that each case must be dealt with on its merits. However, the drug he mainly favors in its treatment is old yellow santonin in 5-grain doses night and morning rubbed up in a teaspoonful of olive or almond oil. If the patient does not tolerate the oil the santonin may be given in the form of soft gelatin capsules. When such treatment is continued for a week recent or mild cases are improved. Of course chronic cases are more obstinate and it may be necessary to repeat the treatment at intervals, as soon as the patient appears to be retrogressing. According to Begg new colorless santonin has no therapeutic action on the complaint and only old santonin, the older the better, is of use. Moreover, the santonin should have been exposed to sunlight for six months at least. Begg does not appear to place much faith in mouth disinfectants, although some authorities have stated that an effective disinfectant is of much value. The book is well printed and bound, contains some good illustrations, and may be recommended to those who practise in regions in which the exceedingly troublesome disease sprue is present.

An Introduction to the Study of Infection and Immunity, including chapters on Serum Therapy, Chemotherapy and Serum Diagnosis. For Students and Practitioners. By Charles E. Simon, B.A., M.D., Professor of Clinical Pathology and Experimental Medicine at the College of Physicians and Surgeons, Baltimore, Maryland. Illustrated. Price $3.25 net. Philadelphia and New York: Lea & Febiger, 1912.

This book was written with the view of providing an adequate means whereby the general practitioner might familiarize himself with the essential basis upon which the new science of immunology has been established. The author follows the teachings of the German school more than that of any other school, and while allowing that to Wright is due the actual introduction of the method of antityphoid vaccination in common use severely criticises his teachings as to the value of the opsonic index. Of course it is generally argued by Wright and his disciples that in many instances in which the opsonic index fails this is due to the fact that the method is not employed properly. Be this as it may, it is more than probable that the technique of the method is too elaborate for general use and that this alone will obviate its employment by the general practitioner. The side chain theory is discussed at considerable length and Simon is of the opinion that this theory accounts satisfactorily for the formation and specific action of the antibodies and thus far the origin and mode of action of some of the most important defensive factors of the animal body, and accordingly he considers some of the more general aspects of the problems of immunity upon the basis of Ehrlich's views. As may be imagined the author is a somewhat enthusiastic advocate of salvarsan in the treatment of syphilis and suggests that it may be of value also in the treatment of some non-syphilitic maladies. The book affords a satisfactory review of a science which is as yet in its infancy and concerning which it would be rash to make dogmatic statements. The binding and printing of the volume are excellent and the illustrations are good.

A Reference Handbook of the Medical Sciences. Embracing the Entire Range of Scientific and Practical Medicine and Applied Science. By Various Writers. Third Edition, Completely Revised and Rewritten. Edited by Thomas Lathrop Stedman, A.M., M.D. Complete in Eight Volumes. Volume One. Illustrated by Numerous Chromolithographs and Six Hundred and Eleven Fine Half-Tone and Wood Engravings. Price $7.00 net. New York: William Wood and Company, 1913.

At no time more than the present has there been such a pressing need for a work of reference that would cover the entire field of medicine and of auxiliary and other related sciences. No introduction is necessary for the "Reference Handbook" which in its two former editions and supplements has filled the important place of a standard work in the medical library. The enthusiasm with which the many problems of disease have been probed during the past ten years, both in the laboratory and in the clinic, and the vast additions that have been made to the literature of medicine during this period have rendered necessary a complete revision of this work. It will suffice to point out a few of the special features of the latest edition, the first volume of which has just appeared. The work appears in a new garb, with an improved quality of paper and a clearer type, so that the page is decidedly more attractive. A number of new features have been introduced. There have been provided a larger number of cross references, and under these in many cases there is given condensed information which may obviate the necessity of referring to the main article. The history of medicine, including brief biographies of noted medical men of the past, forms an important addition to this work. There is a more complete discussion of zoological topics and the articles on health resorts have been greatly amplified. In glancing casually through the first volume one notes the large amount of space that is accorded to subjects in which there have been important developments within recent years. It is not necessary to refer to more than a few of these. In the article on anesthesia and analgesia the latest theories on sensibility, including the rôle of the optic thalamus with reference to the affective tone of sensations, are fully discussed. The article on general anesthesia details with the aid of numerous illustrations the newest methods of administering anesthetics, particular prominence being paid to the use of warmed ether by the drop method; the methods of intratracheal, intravenous, and rectal anesthesia are also described. The recent developments in the surgery of the arteries are described in an article of fourteen pages. A liberal allotment of thirty-three pages is given to the subjects of acute and chronic arthritis, which are presented with the aid of many excellent photomicrographs, photographs of patients and of apparatus, and radiograms. A thorough summary of the present knowledge of pathogenic bacteria is given in an article, really a treatise, of fifty pages, which is embellished with three superb plates. Bacteriological technique is dealt with in a most exhaustive manner in a separate article. In the articles dealing with the abdomen, the surgical anatomy, injuries, the regional anatomy of its organs, the various types of abdominal incision, and the diagnosis of abdominal tumors, are all fully discussed. These and a number of other articles appeared in the former edition, but have been revised and modernized for this. A large number of valuable data are presented in an article on age—data for estimating the age of fetuses, the eruption of the teeth, the order of ossification of the carpal bones, the stages of anatomical age as indicated by the ossification in the wrist, the number of teeth and wrist bones in relation to age and sex, the chronological age of the first menstruation, and the varying ages of puberty. Anaphylaxis is discussed in its many theoretical and practical aspects. Among other important articles may be mentioned the following: the Basle anatomical nomenclature, the history of anatomy, angina abdominis, angina pectoris, animal experimentation, medical anthropology, anthropometry, antitoxins, appendicostomy, argyria, diseases and injuries of the arm and forearm, the army medical department, the army field service, army medical statistics, cardiac arrhythmia, asthma, ateliosis, gastrointestinal autointoxication, automatic actions, and the hygienic relations of the automobile. This brief enumeration conveys some idea of the comprehensive nature of this work. The bibliographies appended to some of the longer articles are a valuable aid in the further investigation of the subject. Of eminently practical value are the short articles on the materia medica, including the latest remedies, and the succinct descriptions of mineral springs and health resorts.

Christ Among the Cattle. A Sermon. Preached in the First Congregational Church, Portland, Oregon. By Frederick Rowland Martin. Sixth Edition, Revised and Corrected. Price 60 cents. Boston: Sherman, French & Co., 1912.

This sermon, which has had a considerable vogue, is to a large extent a consideration of the vivisection question regarded from the standpoint of religion and sentimentalism. The matter is discussed eloquently, but in so one-sided a manner that it loses a great deal of its force and will hardly commend itself to the scientific physician or to the unbiased intelligent layman. There are many much stronger antivivisection arguments than the author furnishes here.

# Society Reports.

## REPORTS FROM THE TUESDAY CONFERENCES OF THE NEUROLOGICAL INSTITUTE OF NEW YORK.

FIRST DIVISION—DR. JOSEPH COLLINS.

**Acute Bulbar Paralysis.** — Dr. Collins, in presenting the case, said that incomplete, or better said, atypical, cases of bulbar paralysis were rare. Chronic degenerative lesion of the neuclei in the ventral portion of the oblongata is accompanied by a group of symptoms which is typical, and no one, not even the beginner in diagnosis, can fail to put proper interpretation upon them. Not so, however, with acute lesions in the oblongata in which neither the onset of the symptoms nor their association is characteristic or typical. A young man who came to the Neurological Institute in October of this year is illustrative of this. A bookkeeper by occupation, 35 years old, related that in March of the present year he was suddenly seized with drowsiness, a sense of apprehension, and faintness while seated at his desk. He soon got a glass of spirits which he thought revived him. He at once noted a numbness and tingling in the fingers of the right hand, and he soon experienced difficulty in speaking (phonating) and in swallowing. These symptoms have continued until the present time. When he attempts to speak the face remains curiously immobile and expressionless and he does not succeed in making any tone save here and there an irregular note. He can whisper very distinctly. On drinking a glass of water he swallows the first two or three mouthfuls very well, but after that the act of deglutition is very slow, and if he persists the fluid is likely to regurgitate. It is much the same when he takes solids; consequently, it takes him an extremely long time to eat his meals. He can make rapid and extensive movements of the tongue both within and without the mouth, and he is able to pucker the lips. There is no indication of atrophy. A curious symptom is a deficient innervation of the left side of the face, especially the upper part, contrasted with the right. This is the only evidence of paralysis save that revealed by the laryngoscope. This condition is best depicted by the accompanying illustrations.

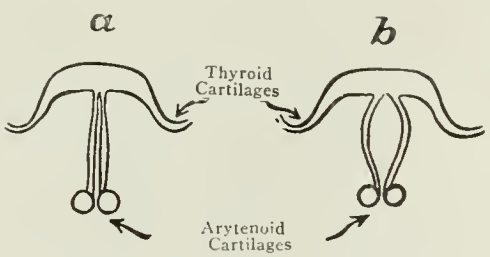

FIG. 1.—Diagram of the vocal cords; *a*, normal closure; *b*, incomplete closure in the case reported.

The patient is unable to speak save in a whisper, here and there a tone being added to the attempts at vocalization. When he attempts to speak, the vocal cords in their upper one-half remain flaccid; in the lower half the arytenoids seem to contract, and as a result of this, the space between the vocal cords becomes ovoid in shape, the wide end of the ovoid being above. In other words, there is a paralysis of the superior laryngeal nerve.*

The only other striking symptom which the patient presents is a profound cyanosis of the finger-tips extending through the two proximal phalanges. This is not a constant condition. It occurs most conspicuously when the hands are exposed to cold or when the patient gets very fatigued. Occasionally it displays itself only in alternate fingers, but as a rule all the fingers are involved. The patient can use all his extremities dexterously and with average strength, and the tendon jerks are not perceptibly altered. There is no disturbance of any variety of sensibility, and the vegetative functions of the body are not particularly abnormal. The electrical reactions in all the muscles susceptible to examination are quite normal, and there is nothing approaching the so-called "myasthenic reaction."

In brief, then, the conspicuous symptoms which this patient displays are: (1) aphonia; (2) dysphagia; (3) immobility of the facial muscles which gives an extraordinary masklike appearance to the face, especially to the lower half; (4) cyanosis of the extremities, particularly the finger-tips; (5) paralysis of the vocal cords; all coming on abruptly after an attack resembling syncope, in a young man who had had, five years before, a luetic infection which apparently ran an uneventful course, and in whom, after the occurrence, examination of the blood and the cerebrospinal fluid revealed no evidence of the activity of the infection. Moreover, there was no indication of disease of the blood-vessels, so far as such condition was revealed either by palpation or by rise of blood pressure. The patient has been under observation for about two months, and during that time his condition has not materially altered save that he feels better and stronger, and he is able to do some clerical work. When he attempts to use the muscles supplied by the oblongata, however, his bulbar symptoms become more striking.

Interpretation to be put upon such symptoms is, I believe, that there has been thrombosis in those terminal branches of the vertebral artery within the oblongata, known as the bulbar arteries, and that this disorder of circulation—comparatively slight though it probably is—has caused a disorder, organic in nature, of the nuclei of the ninth and tenth nerves particularly. The initial symptoms which he had, namely, the drowsiness and the syncopal sensations, are to be interpreted, it is conjectured, as the result of a disturbance of the entire intracranial circulation resulting from the thrombotic deposit in the bulbar arteries, which in turn was incidental to a luetic endarteritis.

It is now fairly well proven that in luetic endarteritis, whether it be extensive or narrowly confined to small or large blood-vessels, the laboratory tests to reveal the existence of infection are, as a rule, negative. In some instances the Wassermann test in the blood may be positive, but rarely does the cerebrospinal fluid react with any of the four tests (Wassermann test, globulin, reduction of Fehling's solution, and increase of lymphocytes) which we have learned are so valuable in the diagnosis of the organic nervous diseases of the cerebrospinal axis that flow out of syphilis. So that in this instance, interpreting the case, as we do, as one of luetic endarteritis, we are not deviated from that opinion because of the absence of these indications of the fundamental infection.

The part that alcohol played in the genesis of his disease was undoubtedly an important contributing one; but, alone, it is insufficient to produce the condition which exists. Alcohol, it is well known, causes a variety of polioencephalitides which have distinctive clinical features. The pathological process in this instance, however, is not an inflammatory state, but is a very mild degenerative state analogous to that of a slight and slowly progressing myelomalacia. It is a condition which may well result, under appropriate medical treatment, in a very considerable degree of recovery.

On account of the possibility of the condition being due

*In speaking of the faulty tension of the vocal cords this condition has been ascribed above to impaired innervation by the external laryngeal nerve. It is also to be noted that the thyroarytenoid muscle has been said to take some part in producing tension of the cords. Some anatomists, indeed, state that this muscle is the one chiefly responsible for their action (Quain). This, of course, is innervated by the recurrent laryngeal nerve.

to an involvement of the recurrent laryngeal nerve stereoscopic .r-ray examination of the chest was made by Dr. Cole. The abnormalities he reports are the following: Just below the arch of the aorta, which by the way is normal, there was an indistinct spherical shadow about an inch in diameter, and a slight thickening around the roots of both lungs. He does not believe that there is an aneurysm and this small mass seems to be entirely independent of the aorta and too far to the left to interfere with the recurrent laryngeal nerve.

Even did this involve the recurrent laryngeal nerve the lesion would be unilateral instead of bilateral as in our case, and also there would probably be some failure in the adduction of the cords at their insertion into the arytenoid cartilages.

SECOND DIVISION—DR. FREDERICK PETERSON.

**Compression of the Spinal Cord; Relief by Operation.**—Dr. Foster Kennedy showed the following case: P. M. H., male, age 27, was admitted to hospital on January 30, 1912, complaining of inability to use his right arm and right leg in a normal manner. His previous history had been good. On November 2, 1911, the patient fell down an elevator shaft a distance of 35 feet. It is supposed

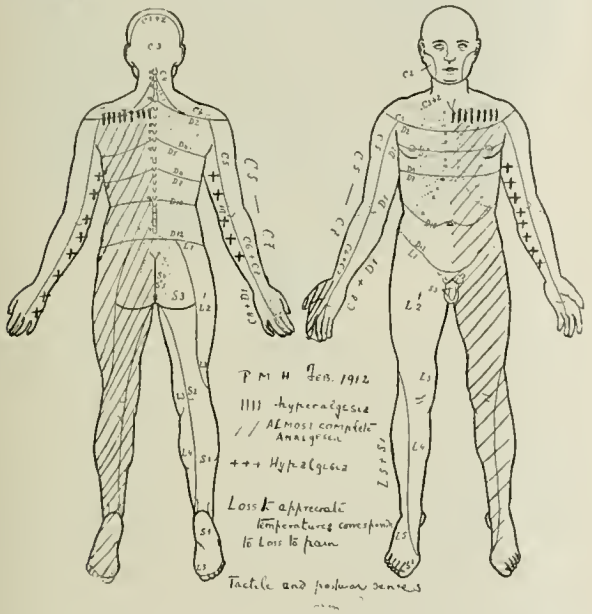

FIG. 2.—Sensory disturbance in a case of compression of the spinal cord.

that he alighted on his head and right knee. Some hours later he recovered consciousness in a hospital. However, for two or three weeks he remained more or less constantly delirious. It was noted during this time that all four limbs appeared paralyzed. The right side was entirely paralyzed, whereas the left limbs were rarely and but slightly moved. However, the left rapidly improved and in two weeks was apparently entirely well with the exception of some residual weakness in the left hand.

As a result of the fall he fractured the right patella. The right knee was encased in plaster-of-Paris. Some weeks after the accident the patient noted that his right arm was adducted to the chest and bent at the elbow. Up to the beginning of December, 1911, he had no power in his right arm and leg. The first movement returned was adduction of the little and ring finger, then by rolling movement he became gradually able to extend the forearm to an obtuse angle. On removing the cast from the right knee he was found to be unable to move the knee. The first movement returned in the right leg was that of dorsiflexion of the toes. He had no severe pain beyond a pricking sensation in the left thumb and the radial aspect of the left forearm. He has had frequent jerking of his right leg. When he bends his neck suddenly there is a pins-and-needles sensation in both arms and occasionally in the feet. He has had no sphincter trouble.

Patient's neck is turned slightly to the right, with moderate elevation of the chin. All the fingers of the right hand are flexed, the little finger to the greatest and the index finger to the least degree. The right arm can be voluntarily elevated to not quite a right angle. There is a slight ankylosis of the right shoulder joint. Right triceps, deltoids supra, and infraspinatus muscles are very weak. Weakness of flexor of the right wrist. Weakness of extensors of right wrist and to a lesser degree those of the left wrist. A considerable degree of atrophy is present in all these muscles. Weakness of the extensors of the right thigh and the right peroneal muscles. In consequence of which there is a drop foot on the right side. The left pupil is dilated and larger than that on the right side. It dilates badly on shading. Otherwise, his cranial nerves are normal. His gait is spastic and his station unsteady.

Reflexes.—Knee-jerks are increased, the left being the greater. Ankle-jerks ditto. Ill marked ankle clonus on both sides. Double extensor response in the plantar reflexes. Abdominal reflexes absent. No sphincter trouble. The sensory system shows almost complete abolition of pain and temperature appreciation over the left side of the body below the level of the second dorsal spine, and to a lesser degree also along the radial borders of both arms. The tactile and postural sensibility are normal (see chart). The lesion therefore is evidently one producing damage to the right side of the cord in the lower cervical region producing ipsolateral motor paralysis and contralateral sensory paralysis by reason of damage to the fibers conducting pain and temperature sensibility crossing from the left to the right side of the cord.

A skiagraph by Dr. Cole shows that the fifth and sixth cervical vertebræ are displaced backward and that there is apparently a bridge of bone between them, the fifth vertebræ being tilted forward on the sixth. There is a very great flattening in the fifth and an irregularity in the sixth foramina.

On February 8 Dr. Elsberg operated. An incision 10 cm. long was made upward from the level of the seventh cervical spine, which was first exposed. The fifth and sixth spines were not in the normal line but lay very deeply to one side, so that considerable muscle tissue had to be divided before they could be seen. The spine of the sixth vertebra was first removed and the corresponding laminæ were found to be very deep and abnormally movable. The spines and laminæ of the fifth and sixth vertebræ were removed after considerable difficulty. The theca was very thick and did not pulsate. Incision of the theca exposed the pia distended with fluid; a small opening was made in the pia and a large amount of fluid under considerable pressure spouted up 6 inches from the wound. It was evident that the fluid came not from above but from below. The exposed cord was much flattened, being at least 2 cm. broad. It felt normal in consistency but was decidedly angulated at the level of the body of the fifth cervical vertebra. As the effect of the removal of the spines and laminæ was felt to be sufficient to relieve any pressure on the cord and as there was nothing abnormal such as a hemorrhage to be felt in the cord, the operation was stopped. The operation was well borne.

On February 12 it was found that pain stimuli could be appreciated on the dorsum on the left foot; the abdominal reflexes were present for the first time on both sides, that on the left being greater than that on the right. Power in the left leg had improved and the plantar reflex on the left side had become normal in type.

On March 6, 1912, spasticity of the legs has become much less marked. Patient's gait has correspondingly improved. The spasticity in the right arm completely disappeared. Grasp in the right is firm though still weak; the left upper extremity shows gradual though steady increase in power. The electrical response of all the muscles of the right arm is prompt; this in the triceps being a marked improvement over the condition existing prior to surgical interference. Pain and temperature are readily appreciated on the dorsum and sole of the left foot. Over the whole of the left lower extremity the patient distinguishes between sharp and blunt instruments; also he is able to distinguish the warmer of hot and cold tubes, but there is a great deal of confusion in interpreting successfully whether the sensation is actually hot or actually cold.

THIRD DIVISION—DR. PEARCE BAILEY.

**Aneurysm of the Vertebral Artery.**—Dr. Bailey presented a pathological specimen of this condition giving the history of the case. The patient, R. W., 37 years of age, a druggist, was admitted to the hospital October 29, 1912. There was paralysis of both arms and legs and stiffness and rigidity of the neck. The history given was as follows: For the past two or three years he had some difficulty in raising the right arm when reaching for bottles on the shelves in his drug store. Although he was right handed he soon came to use the left arm in preference to the right on account of weakness of the right. Several years before this he had noticed some stiffness and rigidity of the neck.

On June 29, 1912, he began to experience severe, sharp, shooting pains in the back of the neck, radiating to the top of the head and which were more or less constant. Since then the pains have been severe enough to require morphine for relief. At this time he also had some tingling and numbness of the right hand with some weakness, a condition which gradually increased until he was almost robbed of the use of the right arm. At the same time there was some beginning weakness of the left hand.

Fig. 3.—Skiagraph of cervical spine, showing a displacement of the fifth and sixth cervical vertebræ.

Since June he has lost sexual power. About a month before admission he experienced tingling sensations in the right foot associated with some weakness. This gradually progressed, although he was still able to walk until a week before admission, when he became rapidly worse so that in three days he was unable to walk or to use his arms. The pains in the neck at this time became very much more severe.

On admission to the hospital he was paralyzed in all four extremities. This paralysis was flaccid with exaggeration of the knee jerks and ankle clonus. There was also an anesthesia of the body which extended up into the cheeks, corresponding in distribution to that of the second cervical segment. Movement was so painful that

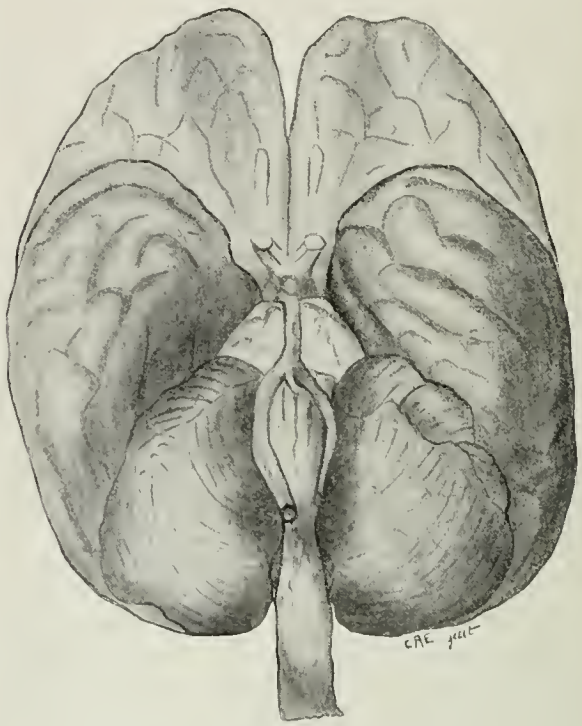

Fig. 4.—Aneurysm of the right vertebral artery with compression of the spinal cord.

the back was not examined. There was retention of urine requiring catheterization. The pupils were very small but reacted to light.

The man died thirty-six hours after admission. His condition while in the hospital was precarious and lumbar puncture was impossible. Death resulted from pulmonary edema with a rising temperature. There was no marked increase of pulse rate and there were at no time symptoms of involvement of the medulla.

The case presented, therefore, symptoms of a long standing irritation and injury to the spinal cord which terminated in an acute and fatal attack which abolished the cord functions at the level of the second cervical segment. During life the most probable diagnosis seemed that of a tumor which had suddenly extended or caused pressure.

Post-mortem findings showed a very extensive condition of aneurysm of the right vertebral artery. This aneurysm accounts practically for all the symptoms, *i.e.* the long standing stiffness and rigidity of the neck until finally an increased distention of the aneurysm fatally injured the spinal cord at the indicated level. At the point of compression the cord was very soft, compressed, and dark in color. On section it was extremely soft and dotted with hemorrhagic areas. Microscopically it showed great destruction especially of the gray matter. The cord section showed some hemorrhages and the most probable explanation seems to be that of an anemic necrosis from pressure by the aneurysm which deprived the cord of its blood supply. The affected vertebral artery was the seat of an extensive endarteritis and also some endarteritis in the other cerebral vessels. There was also some evidence of degenerative disease in the spinal laminæ.

## NEW YORK ACADEMY OF MEDICINE.

*Regular Meeting, Held January 2, 1913.*

THE PRESIDENT, DR. WILLIAM M. POLK, IN THE CHAIR.

**Quarantine in the Maritime Cities of the United States.**—The Public Health, Hospital, and Budget Committee of the New York Academy of Medicine made this report, which is briefly summarized as follows: 1. Because of the international character of modern commerce the tendency of the last fifty years has been from local and provincial regulations to uniform national and international rules and laws. 2. Prior to 1893, there was no national system of quarantine in the United States. Since that time 47 ports have come under the control of the Public Health Service of the Treasury Department, so that there are at present only three ports whose quarantine stations are managed by local and state authorities. 3. In order that the United States may be a responsible party to international agreement regarding quarantine regulations, it must have control and supervision over all the ports of the country. 4. The record of the past work of the United States Public Health Service is such as to insure confidence in its efficiency. It has a well trained staff of medical officers and is equipped for efficient quarantine administration. 5. Quarantine work is essentially scientific in its nature and can be carried on efficiently only if the tenure of office is independent of changes in administration and of politics. 6. From the point of view of convenience, efficiency, and uniformity of administration, economy, and law, the arguments are in favor of a national control of quarantine in all parts of the United States.

*Recommendations.*—The Committee on Public Health, Hospitals, and the Budget of the New York Academy of Medicine recommended: 1. That the Quarantine Station at the port of New York be transferred to the United States Public Health Service; and 2. That the Council of the New York Academy of Medicine take appropriate action to further actively the above recommendation.

**The President's Address.**—Dr. WILLIAM M. POLK delivered this address (see page 139).

The scientific session was held under the auspices of the Section on Genito-Urinary Surgery, and consisted of a symposium on "Lithiasis of the Urogenital Tract."

**Ureteral Lithiasis.**—Dr. HUGH CABOT of Boston presented this communication and gave a lantern slide exhibit. He called attention especially to the operative treatment of these cases. The decision to undertake an operation for a stone in the ureter must depend upon one's opinion of the extent to which the integrity of the kidney was being menaced. With the present highly developed technique and exceedingly low mortality it was clearly unwise to allow any considerable menace to the integrity of the kidney to continue after the diagnosis had been made. It was permissible to wait in two classes of cases: 1. Those in which the stone was small and could be demonstrated by the *x*-ray to be making reasonable progress down the ureter. 2. There was a not inconsiderable number of what might be called chronic stones in the ureter which had worked their way downward slowly without severe symptoms and which had probably at no time totally obstructed the ureter. In these cases a catheter would usually pass freely to the kidney, and they might be compared to those cases of stone in the common bile duct which occurred in the absence of jaundice. In such cases ultimate removal of the stone must be advised unless the patient was totally unable to withstand any major operation. On the other hand, it was clear that no great urgency existed and that various social and financial affairs might be permitted to influence the decision. Nothing more than reasonable delay should be countenanced as the kidney in these cases was probably always infected and the progress of the infection could not be assumed to be stationary or even slowly progressive. In the operative management of ureter calculi certain general principles might be laid down. There must be a good exposure which would enable one to deal with the ureter freely and without constraint. The ureter must be thoroughly freed so that it could be brought well up into the wound. This was possible except in the lowest portion. It was wise to place a compression clamp upon the ureter some distance above the point at which it was to be opened in order to avoid contamination of the wound with probably infected urine. Contrary to most authorities it was, in his opinion, wiser to incise the ureter an inch or more above the stone. At this point the ureter was almost always dilated and an appropriate instrument could be passed into the ureter and the stone withdrawn backward with the aid of the fingers. The reason for preferring this incision was that at the seat of the stone there was at least some inflammation present and there was liable to be some narrowing of the ureter at that point and incision invited further narrowing. Exception must be made in cases where the ureter was so contracted that the stone could not be removed without breaking it into pieces. Having removed the stone, it was essential to demonstrate that the ureter below this point was free from obstruction. Most of the cases of persistent ureteral sinus were due to overlooked stricture. This demonstration should be made by the passage of a flexible bougi à boule down into the bladder. It was also wise to explore the ureter above, though usually nothing abnormal was found. Should a stricture be demonstrated it should be freely incised and the vertical incision sewed up transversely, so as to increase the calibre of the canal at this point. The closure of the wound in the ureter was an important part of the operation; it seemed unnecessary to allow any leakage to occur. For this purpose he employed double zero plain cat-gut as it did not seem necessary that apposition be maintained for any length of time. The abdominal wound should be provided with a minimum of drainage; he now employed a single small piece of so-called protective tissue and closed the wound snugly about this. This drain should not be removed for five or six days as leakage was apt to occur for several days after the operation. As to the choice of incisions, for stones in the ureter above the pelvic brim an oblique muscle splitting incision was generally satisfactory. The skin incision should be made over the course of the ureter parallel to the fibers of the external oblique and should be sufficiently free to give access to the deeper parts. The fibers of the internal oblique and transversalis could be separated nearly at right angles to the other wound, giving a sufficient field if the stone had been accurately located beforehand. The advantage of this incision over that which cross-cut muscle fibers was the rapidity of the healing, the strength of the scar, and the comfort of the patient. For stones below the pelvic brim a similar incision prolonged downward had frequently been used. To the speaker it did not seem nearly as satisfactory as the incision proposed some years ago by Charles Gibson, which consisted in an incision beginning at or across the median line just above the pubes following the curve of Poupart's ligament outward and turning sharply upward just inside the anterior superior spine. This incision cross-cut no muscle fibers except at its extreme upper end and this was not always necessary. Gibson advised that this flap be dissected freely upward and that the first incision be then met by another following the outer border of the rectus muscles where the various layers of the fascia split to form the sheath. This gave a triangular flap and an excellent exposure. Dr. Cabot said he had gotten an equally good exposure by cross-cutting the fibers of the rectus muscle on the side involved about an inch above their insertion into the pubic bone, thereby giving ample tissue in which to place sutures to reunite the ends. If the patient was placed in the Trendelenberg position the intestines fell away and gave a thoroughly satisfactory exposure of the ureter from the iliac vessels to the bladder wall. For stones situated in the lower inch or two of the ureter this operation was least suited and it seemed as though it should be possible to deal with them by some intravesical method. On the other hand, the calculi which lodged just outside the bladder wall at the beginning of the oblique portion usually lay in a little pocket not directly in line with the ureter. Any method of intravesical incision of the ureter which was to reach these stones must incise the whole ureter and the whole thickness of the bladder wall in order to be effective. This seemed to him unnecessarily mutilating and he had recently removed a stone situated just outside the bladder wall by a technique which seemed worth further trial. The bladder was opened in the middle line above the pubes and a metal instrument passed into the ureteral orifice was arrested at about an inch, though the stone could not be felt. The peritoneum was then stripped from the lateral wall of the bladder and the lower three inches of the ureter identified and freed. The ureter was then opened about three inches above the bladder and by passing the instruments in both directions the stone was dislodged from its pocket and pushed into the bladder. The opening into the ureter and the wound in the bladder were both closed and no leakage had taken place. This approach seemed less difficult than that in which the bladder was not opened as the stone was under better control and the incision in the ureter could be made at a considerably higher point.

**Renal Lithiasis.**—Dr. J. BENTLEY SQUIER, JR., read this paper. After reviewing the various theories regarding the causation of renal calculi he said that from a treatment viewpoint renal calculi might be regarded as aseptic or

septic according to the presence of bacterial inflammation in the kidney. The aseptic stage began with the irritation of the kidney, due to the passage of urine loaded with uric acid or calcium oxalate crystals, continued with the deposit of these crystals in calculus formation and the production of catarrhal or interstitial changes in the kidney, and merged into the septic stage when hematogenous infection occurred. These changes might be insidious and years might elapse before the gamut was run, but the rule was a progressive destruction of the kidney through interstitial changes or by suppuration. Mere minor symptoms should attract attention to the kidneys as the seat of disease. Dr. L. G. Cole, from his vast experience in radiography, stated that most of the cases in which renal calculi had been demonstrated by the *x*-ray had had no symptoms that were sufficiently characteristic to justify an operation and only those that engaged in the ureter or obstructed the pelvis caused typical renal colic. The time was at hand when slight pain in the back, tenderness over the kidney, a sense of weight in the back which was increased by jolting, or the presence of even a trace of albumen, should call for a complete routine examination of the urinary tract. Dr. Squier then related the history of a number of cases which served to illustrate the various symptoms presented by patients suffering from renal calculi. In considering the surgery of nephrolithiasis, the classification of the disease into an aseptic and a septic stage was convenient. The surgery of the aseptic stage comprised the removal of the calculus or calculi with or without drainage of the organ. The surgery of the septic stage required the removal of the calculus, or calculi, with drainage, and, frequently, excision of the diseased kidney. The surgery of the aseptic stage was completed in one stage and might necessitate a primary operation for drainage of renal or perirenal pus collections, with secondary operation for removal of the kidneys. The vertical incision should be made for the aseptic stage. The kidney having been delivered on the loin, it was turned with its convex border pointing outward. The posterior surface was thus exposed. It was preferable to remove calculi through a posterior incision for two reasons: one because there was less hemorrhage, the other because if drainage was necessary its course was straight. With the kidney on the loin, if the calculus could be removed through an incision in the pelvis, it should be so removed. They had learned the advantage of pyelectomy only in the past few years, the fear of a permanent fistula resulting from such an incision having been proven to be groundless. The incision should be made at right angles to the kidney and along the lower border of the pelvis; it should not extend into the ureter. If the calculus was felt before the kidney was opened, it was well to steady it at the lower border of the pelvis and to open the pelvis as indicated, by cutting down upon the stone. If the calculus was small, or multiple, or situated in the calices, the pelvis might be searched with the finger. The incision in the pelvis was closed with fine cat-gut sutures, and the wound was closed with or without drainage as the case might indicate. In the treatment of the septic stage a more complex problem confronted them. The degree of sepsis must influence their operative decision. A mild pyelitis would require removal of the stone with drainage of the pelvis. Extensive suppuration with destruction of kidney tissue would indicate nephrectomy.

**A Portable X-Ray Apparatus.**—Dr. J. Bentley Squier presented this instrument, which consisted of a Tesla coil, a Crookes tube, and a flouroscopic screen of his own design. This apparatus was for use in the operating room and would settle definitely whether or not calculi were present. It was used with the kidney lying on the loin.

**Vesical Calculus.**—Dr. Edward L. Keyes, Jr., read this paper. He stated that the brief survey of the symptoms, diagnosis, and treatment of this condition which he proposed to give was based on personal experience and not on text-book rules. The symptoms began with the history which might or might not include attacks of renal colic, as the stone slipped from the kidney into the bladder. In his experience a minority of bladder stone cases gave such a history. If the patient's history began with such a colic, a greater or less interval of time intervened, during which the stone remained silent in the patient's bladder. This interval might extend to a number of months or even years. When the stone began to irritate the bladder and to cause frequent and painful micturition, or even cystitis, the course of the disease became characteristically remittent. The frequent and painful urination was characteristically more severe by day than by night; more severe when the patient went about than when he sat still. This rule, however, was broken by innumerable exceptions. Analysis of the urine of a patient suffering from stone in the bladder was likely to reveal a few blood cells, though the presence of microscopical blood was not constant. On the other hand occasional slight hemorrhage of prostatic origin, occurring at the termination of urination, and accompanied by a good deal of pain, might be due to stone, but was more suggestive of tuberculosis. Pus might or might not be found in the urine. The symptoms of stone in the bladder, like those of stone in the ureter or kidney pelvis, were often simulated by other maladies. The typical picture of stone in the bladder might be precisely mimicked by renal, or reno-vesical, or prostatic tuberculosis, so that for diagnostic purposes the clinical picture of stone was worth almost nothing at all. Furthermore, some patients could carry a stone in the bladder for years without symptoms. The one symptom upon which some dependence could be placed was "stinking urine" without grave kidney lesion and without retention of urine in the bladder. This stinking urine, without renal or vesical retention, was but rarely seen. A purulent urine that became absolutely clear and free from pus under treatment suggested that no stone was present. Among the definite surgical measures for ascertaining the presence of a calculus in the urinary tract the radiograph stood first and when vesical calculus was suspected one should always have a radiograph taken. The radiograph is singularly negative in the detection of vesical calculi. This meant that certain of these calculi were singularly bereft of lime salts in their construction. An older diagnostic implement was the stone searcher. This in the hands of the expert manipulator was a delicate diagnostic instrument that might do service in persuading irritable patients that they had stones by the briefest manipulation. The cystoscope, like the *x*-ray, was the essential instrument for the diagnosis of vesical calculus. Even the cystoscope was by no means infallible in the diagnosis of stone. Apart from the fact that the examination might fail to reveal a stone in a saccule, it was liable to two grave misinterpretations. An old clot looked exactly like an acid stone, while a stone covered with fibrin often looked exactly like a sloughy malignant tumor. A knowledge of these possible errors and a little experience with the ureteral catheter almost invariably sufficed for a diagnosis. In speaking of treatment, Dr. Keyes said that small vesical calculi, like small ureteral calculi, might pass spontaneously, yet there was not the same incentive to wait for such passage, since vesical calculi might be crushed in a few moments. If the patient was not oversensitive this operation might be performed in the physician's office under local anesthesia. On the other hand, large stones or stones complicated by bladder tumor, or sacculation, or by prostatic hypertrophy, obviously required suprapubic cystotomy for their removal, for the management of complications, and for drainage. There were many stones of moderate size where the question as to the choice of operation arose. Should they perform litholapaxy, or lithotomy? The older generation succeeded very well with the former operation. Dr. Keyes said that his father had performed over two hundred litholapaxies and never lost a patient under sixty years of age. Stones in the bladder were relatively infrequent in this part of the world, while ambitious general surgeons were very numerous, hence these patients were distributed in small numbers to a very large number of operators who had little interest in the various delicate features which these patients presented. Such men did not perform litholapaxy and it was better that they should not. For uncomplicated stones the specialist would continue to prefer litholapaxy to lithotomy on account of the lesser mortality and the greater rapidity of convalescence. The performance of repeated litholapaxies on old prostatics was by no means an ideal procedure, though one occasionally met patients who insisted on this form of treatment. It was to be hoped that the dispute between litholapaxy and lithotomy would continue to be vigorous and interminable; it was also to be hoped that the rival camps would occasionally call a truce and urge subscription to one thesis for the edification of the young: "When in doubt, cut."

**Urethral and Periurethral Lithiasis.**—Dr. Victor Cox Pedersen read this paper. He discussed the pathogenesis and the sites of impaction of urethral calculi, showing that the prostate was the commonest source of such periurethral stones and that abscesses draining into the urethra, just as those draining into the kidneys, ureters, and bladder, originated most endourethral calculi. Urethral lithiasis affected child and adult alike. In children these stones were usually migratory, impacted, endourethral manifestations. In small children practically all urethral concretions were of intrauterine renal origin, migrating

outward and impacted at one of the normal anatomical constrictions. In adults the cases fell into two groups: first, patients who gave little history until the urethral obstruction suddenly appeared and, second, patients who presented a logical and consecutive story of varying degrees and forms of renal disorder, pain, pus, blood, ureteral colic of migration of the stone into the bladder, vesical irritation of its presence in the bladder, and finally the urethral obstruction, absolute or relative. Slight or partial obstruction might give few symptoms. After describing the physical and instrumental examination of the patient for urethral lithiasis, Dr. Pedersen reviewed a series of cases that he had collected in literature which were interesting and illustrated the condition in both children and adults. He also cited a number of cases of endourethral lithiasis of the prostatic urethra. True prostatic concretions were multiple. They were frequently not suspected until met during prostatectomy, having determined few antecedent symptoms, or they might be associated with chronic prostatitis. The radiograph seemed to reveal two types; one diffuse and of hemp seed size, common in old age; the other showed stones crowded together on both sides of the median line and appeared at any period of life. The symptoms of true prostatic lithiasis might be insignificant and pass unnoticed during life. Large, solitary, or multiple calculi, with prostatitis, might provoke such symptoms as difficult, painful, and frequent urination, pain in the perineum, prostate, and rectum, radiating down the penis and thigh, obstipation and painful defecation, and purulent urethral discharge. Rupture of the stone into the prostatic urethra showed itself as an acute posterior urethritis or as an acute retention, through the size of the stone or the swelling of the mucosa. The diagnosis of true prostatic calculi might be made easily by palpation through the rectum if the stone was large and the prostate atrophic, or if the gland was nodular through multiple calculi which might also add crepitus. The diagnosis might be extremely difficult if the stones were small, centrally located, and individually encysted. The sound would detect any stone that projected into the urethra and should never be omitted. The acoustic explorer, the urethroscope, and the cystoscope were very important and radiography was also of use where other methods failed. The second class of periurethral lithiasis of the posterior urethra concerned deposits in deformities, either anatomical deformities or those due to operative procedures. The treatment of urethral and periurethral lithiasis was preventive and curative. Preventive measures implied the management of errors in general and urinary metabolism characterized by intestinal autointoxication which almost invariably invited colon bacilluria. Prevention also regarded careful after treatment in any urogenital surgical condition so that foci and pockets of precipitation might be properly dealt with. Curative treatment acknowledged two classes of cases—those of emergency and those of election type. Emergency cases were characterized by acute, severe symptoms of obstruction, anuria, and infection during a few days or even hours. Urethral lithiasis was a condition on which the extremes of life tolerated badly and with a fatal issue as an all too common outcome. A large class of cases were of the election type, and the treatment of such cases rested on the presence or absence of complications. If the stone was mobile, recently impacted, and without total obstruction to the urine, most authorities would agree that an effort should be made to pass it forward out of the anterior urethra or backward into the bladder out of the posterior urethra by instrumental or digital manipulation. The disintegration of stones might be rather easily accomplished with the fulgurating wire through the cystoscope in the bladder or through the open end urethroscope in the urethra. The complicated cases which almost always had infection as the primary cause of the complications required open operation, removal of the stones, and drainage of the infected field, which necessarily embraced the anterior urethra, the posterior urethra, and often the bladder secondarily.

Dr. Eugene Fuller said that he did not feel that he could criticize adversely any of the papers read; they were all valuable contributions to the subject. In connection with Dr. Cabot's paper he thought that more emphasis might be laid upon the fact that one could not depend upon the *x*-ray alone in making a diagnosis of lithiasis in the urogenital tract; one should supplement ureteral exploration with the *x*-ray. One should not cut too soon without first trying to dislodge the stone by urethral manipulation. It was remarkable how often these stones could be dislodged by manipulation. In those cases in which the stone could not be dislodged by manipulation cutting should be resorted to promptly. One should cut more promptly in non-infective cases with ureteral obstruction than in those cases in which the stone was in the kidney. In the latter condition where the stone was not producing any obstruction, the patient might be kept under observation, deferring the issue of an operation until the development of symptoms might make it indicated. In renal cases one could get the greatest range of symptoms. In one instance in which he had been asked to operate immediately upon a woman admitted to the City Hospital in a serious septic condition, with a large tumefaction in connection with the left kidney, suppression of urine and the kidney in an advanced state of suppuration, the woman had complained of no pain until four days before her admission to the hospital, although it was evident that the condition must have existed for years. Dr. Fuller agreed with Dr. Keyes that lithopaxy was the operation of choice where the operator was competent in the majority of cases of stone in the bladder; where stone formed secondarily to prostatic obstruction it was not the operation of choice.

Dr. Charles H. Chetwood said that the most important fact brought out by this symposium was that many cases did not bear the markings of the classical features, and that it was only by modern diagnostic methods and technical skill that these conditions could be recognized. Apropos of these cases of renal lithiasis Dr. Chetwood recalled an instance in which he operated upon a patient removing fourteen stones from the kidney, one having migrated through the cortex and tissues without producing any symptoms referable to the kidney in face of the fact that at the time the man had an infected kidney. The causation of stone in the kidney, classified as Dr. Squier had stated, was evident in the case of secondary calculi, but had not yet been fully explained in the case of primary stone. In the light of recent knowledge and experience that infarcts might appear from some distant focus of mysterious origin and deposit in the kidney, it seemed that they had in these minute lesions a possible explanation of latent bacteria, with or without infection, which might be the focus of a primary renal calculus. With regard to the stone in the ureter this was often a secondary and not a primary cause of the clinical picture. Dr. Chetwood showed interesting *x*-ray plates taken of a patient who presented the classical symptoms of ureteral stone, with colic, etc., and the diagnosis was promptly made. The *x*-ray showed the presence of a small stone in the lower end of the ureter, evidently not the cause of symptoms. Injecting the ureter with collargol a stricture was shown to be present (5 c.m.), which could be passed with the catheter, and another 20 c.m. through which the catheter could not be passed. After waiting a few days a second attempt to pass the bougie was successful, and, passing both strictures, it was possible to dilate the ureter. The kidney on this side had not been draining and there was a large hydronephrotic sac which then emptied itself. The patient made a satisfactory recovery from the acute condition. An important conclusion to be drawn was that the rôle of the operator was a secondary one in many instances. Operators were many; preoperative diagnosis was very necessary, assisted by the radiograph and the cystoscope, with a correct interpetation of all the findings; it was the man behind the cystoscope who did the work.

Dr. Martin W. Ware said that, in his opinion, the previous speakers had not made sufficient reference to the question of indications. Notwithstanding the fact that they might see these stones it was necessary that certain indications should be present which called for operative interference. Certain principles had been laid down by Israel which were worthy of repetition, and they were especially valuable when used in conjunction with the *x*-ray, the cystoscope, and other diagnostic methods. One had to operate when in the presence of vital indications. One should operate in the absence of vital indications when it seemed evident that damage to the kidney was forthcoming. Three indications should serve as a guide. When the stone was located by means of the *x*-ray it did not mean that the operator was necessarily impressed to operate. Israel had stated that the mortality of 4 per cent. was staring one in the face when he undertook a nephrotomy; statistics did not insure a man against his succumbing to the operation. Aside from the urgent indications there were those that were not so vital. Many patients with stone had persistent neuralgias, dyspepsias, attacks of colic, a loss of their general health—they might not have any vital indications present, but they had symptoms which prevented them from pursuing their calling and earning a livelihood.

Dr. Hugh H. Cabot of Boston, in closing the discussion, said it was difficult to define what was meant by vital indications; did vital indications show how much damage was done the kidney? He doubted whether they had the means

at their disposal of determining how much damage had been done the kidney. An obstruction in the ureter presupposed damage to the kidney. It did not seem to him wise to wait for vital indications. Dr. Cabot did not believe that they ever saw within recent years a mortality as high as four per cent; the mortality to-day was about one-half per cent.

## STATE MEDICAL EXAMINATION QUESTIONS.

### Arkansas State Medical Board.

*May 14 and 15, 1912.*

#### ANATOMY.

1. Name the bones of the face, describing the inferior maxillary.
2. Describe the shoulder-joint.
3. Describe the patella, giving muscular and tendinous attachments.
4. Give origin and insertion of trapezius muscle with nerve and blood-supply.
5. Name the parts severed in amputation of leg 4 inches below knee.
6. Give the anatomic divisions of the alimentary canal.
7. Give name and course of vein involved in varicose veins of leg.
8. Describe the circle of Willis.
9. Describe the rectum, giving nerve and blood-supply.
10. Give origin and distribution of pneumogastric nerve.

#### PHYSIOLOGY.

1. Describe a red blood-corpuscle and tell of its functions.
2. Describe a white blood-corpuscle and tell of its functions.
3. Describe the fetal circulation.
4. Describe the circulation through the heart and lungs.
5. Describe a cross-section of the spinal cord in the mid-dorsal region.
6. Describe the fifth cranial nerve.
7. Describe the large intestine and tell of its functions.
8. Name all the known functions of the liver.
9. Describe the kidneys and tell of their functions.
10. Describe the skin and tell of its functions.

#### CHEMISTRY.

1. Give names and symbols of elements in halogen group, stating why so called.
2. Name three alkaloids of opium most used in medicine, giving dose of each.
3. Give test for strychnine and treatment for an overdose.
4. How is potassium iodide made? Give formula.
5. Give chemical formula of lunar caustic, naming antidote.
6. Give chemical composition of urine, stating normal amount of urea excreted in twenty-four hours.
7. What are the enzymes? Give their functions.
8. What are proteins and from what are they developed?
9. What is pyroxilin and how produced?
10. Complete the following formula: $NaNO_3$ plus $H_2SO_4$=?

#### MATERIA MEDICA.

1. Define an aperient and give an example.
2. Define a vascular contractor and state uses.
3. Define a vascular dilator and state what drug you consider the most valuable as such.
4. Define a solvent and excipient and give an example of each.
5. What is meant by the physiological effect of a drug?
6. Name and give dose of the most powerful hydragogue cathartic.
7. Name the three most-used preparations of opium, and state how much of each represents 1 grain of opium.
8. Give primary and secondary effects of carbolic acid when locally applied.
9. What change takes place in morphine after having been kept for some time in solution?
10. Name the principal remedy used to promote the absorption of morbid products.

#### THERAPEUTICS.

1. Differentiate between materia medica and therapeutics.
2. Differentiate between empirical and rational therapeutics.
3. What is meant by suggestive therapeutics?
4. Name a remedy that is especially indicated in the stage of resolution of pneumonia.
5. Name objective and subjective symptoms of phenol poisoning.
6. How would you treat such a case?
7. Name an antidote for each of the following, and state whether this is physiological or chemical: arsenic, opium, copper, and strychnine.
8. What therapeutic agent liberates formaldehyde in the urine? State in what class of cases it is indicated.
9. In case of sudden collapse, name the quickest and most efficient remedy, and give its mode of administration.
10. Describe the technique in the administration of antimeningitis serum.

#### PATHOLOGY.

1. Define gangrene and name varieties.
2. Describe briefly the changes which take place in atrophy and those which occur in degeneration.
3. What are usual methods of metastatic extension of sarcoma and carcinoma?
4. What conditions are most commonly accompanied with increased blood-pressure and what are the results if this increased pressure is maintained for a considerable time?
5. State briefly the pathologic changes found in pellagra.
6. State briefly the changes that take place in the entire organism as a result of chronic nephritis.
7. What are the principal parts involved in acute anterior poliomyelitis?
8. What are the most common pathologic conditions found in scarlet fever?
9. Give the pathology of chronic gastritis.
10. Give pathology of scorbutus.

## ANSWERS.

#### ANATOMY.

1. *Bones of the face:* Two nasal, two superior maxillary, two lacrymal, two malar, two palate, two inferior turbinated, vomer, and inferior maxillary.

*Inferior maxilla* consists of a body and two rami. The body is horse-shoe shaped and contains the lower teeth; externally it presents the symphysis, mental process, mental foramen, incisive fossa, and external oblique line; internally it presents the four genial tubercles, sublingual fossa, internal oblique line, submaxillary fossa. The alveolar border has sixteen cavities for teeth. The ramus is quadrilateral, and presents the inferior dental foramen and a spine. Above it has the coronoid and condyloid processes, separated by the sigmoid notch. The *muscles attached* are: Levator menti, depressor labii inferioris, depressor anguli oris, platysma myoides, buccinator, masseter, orbicularis oris, geniohyoid, geniohyoglossus, mylohyoid, digastric, superior constrictor of pharynx, temporal, internal and external pterygoids.

2. The shoulder-joint "is an enarthrodial joint formed above by the glenoid cavity of the scapula and below by the head of the humerus. Its ligaments are—glenoid, coraco-humeral, and capsular. The *glenoid* surrounds the edge, deepens the glenoid cavity, and is continuous above with the long head of the biceps tendon. The *capsular ligament,* extensive and loose, arises above it from circumference of glenoid cavity behind the ligament, is attached below to the anatomical neck of humerus, and is pierced by tendons of two or three muscles. The *coraco-humeral,* or *accessory,* is a fibrous band which extends obliquely downward and outward from the coracoid process to the anterior part of great tuberosity, strengthening the capsular ligament."—(Young's *Anatomy.*)

3. The *patella* is a flat, triangular bone situated in front of the knee-joint; it is said to be a sesamoid bone developed in the tendon of the quadriceps extensor. Its anterior surface is convex and shows perforations for nutrient vessels; it is separated from the skin by a bursa. Its posterior surface is smooth and oval-shaped, and has two facets separated by a vertical ridge; these facets articulate with the two condyles of the femur. The superior border gives attachment to the rectus and crureus; the lateral borders give attachment to the vastus externus and vastus internus. The apex gives attachment to the ligamentum patellæ. The anterior surface is covered by the tendon of the quadriceps extensor, which is continuous below with the ligamentum patellæ.

4. Trapezius. *Origin:* External occipital protuberance, inner third of superior curved line of occipital bone, liga-

mentum nuchæ, spinous process of seventh cervical and all the dorsal vertebræ and corresponding portion of supraspinous ligament. *Insertion:* Outer third of posterior border of clavicle, inner margin of the acromion process, and posterior border of spine of scapula. *Nerve-supply:* Spinal accessory, and branches from the anterior divisions of the third and fourth cervical nerves. *Blood-supply:* Superficial cervical, posterior scapular, transversalis colli, and supra-acromial arteries.

5. The parts severed in the amputation of the leg, four inches below the knee, are: Skin, fascia; tibialis anticus, extensor communis digitorum, extensor proprius hallucis, peroneus longus, peroneus brevis, gastrocnemius, soleus, plantaris, flexor longus digitorum, flexor longus hallucis, and tibialis posticus muscles; long saphenous vein, short saphenous vein, anterior tibial artery and veins, posterior tibial artery and veins, and peroneal artery and veins; anterior tibial nerve, posterior tibial nerve, peroneal nerve, and short saphenous nerve or its branches; tibia and fibula and interosseous membrane.

6. *Anatomic divisions of alimentary canal:* Mouth, pharynx, esophagus, stomach, small intestine (duodenum, jejunum, and ileum), large intestine (cecum, ascending colon, hepatic flexure, transverse colon, splenic flexure, descending colon, sigmoid flexure, rectum).

7. The veins involved in varicose veins of the leg are the saphenous veins.

The SAPHENOUS VEINS are formed from the dorsal venous arch.

The *internal saphenous* begins at the inner end of this arch, on the inner side of the foot; it passes upward in front of the internal malleolus, then upward and backward with the internal saphenous nerve, behind the internal condyle of the femur, then upward and outward to the inner side of front of thigh, through the saphenous opening, to empty into the femoral vein.

The *external saphenous* begins at the outer end of the arch, on the outer side of the foot; it passes upward behind the external malleolus, up along the outer side of the tendo Achillis, with external saphenous nerve, to the popliteal space, where it enters the popliteal vein.

8. The *circle of Willis* is an arterial anastomosis situated at the base of the brain. It is formed: In front by the two anterior cerebral arteries (branches of the internal carotid), which are connected by the anterior communicating artery; behind, by the two posterior cerebrals (branches of the basilar artery), which are connected to the internal carotid on each side by the posterior communicating artery.

9. The *rectum* is the lowest part of the alimentary canal, and extends from the sigmoid flexure to the anus. It is about six inches in length, and is divided into three portions. The upper half only is invested with peritoneum. The upper third rests upon the sacral plexus and the pyriformis muscle; the middle third is in relation with the bladder, prostate, and seminal vesicles (in the female with uterus and vagina); the lower third is surrounded by the sphincters. It is not sacculated. *Nerve supply:* Sympathetic plexuses (inferior mesenteric and hypogastric), fibers from the second, third and fourth sacral nerves. *Blood supply:* Superior, middle, and inferior hemorrhoidal arteries and veins.

10. PNEUMOGASTRIC NERVE. *Superficial origin:* Groove between restiform and olivary bodies. *Deep origin:* Nuclei in floor of fourth ventricle. *Course:* Outward across the flocculus, to jugular foramen through which it passes; here it is joined by the accessory portion of the spinal accessory nerve. As it goes down the neck it lies in front of the rectus capitis anticus major and longus colli muscles. It passes in the carotid sheath behind and between the artery and vein. In the thorax the nerve on each side runs a different course. The *right* passes between the subclavian artery and vein, by side of trachea to root of lung, behind esophagus, through esophageal opening in diaphragm to posterior surface of stomach. The *left* passes between the subclavian and carotid arteries, in front of arch of aorta to root of lung, along anterior surface of esophagus, through diaphragm, to anterior surface of stomach. *Distribution* is shown by the names of the branches: Meningeal, auricular, pharyngeal, superior and inferior laryngeal, cardiac, pulmonary, esophageal, and gastric.

PHYSIOLOGY.

1. *The red blood-corpuscles* are biconcave discs, about 1-3200 of an inch in diameter; they are nonnucleated, and there are about 4,500,000 or 5,000,000 of them in each cubic millimeter of blood. They are elastic and soft, and their shape is changed by pressure, but is promptly regained on the removal of the pressure. Their color is yellowish. They contain hemoglobin. They carry oxygen from the lungs to the tissues.

2. The *white blood-corpuscles* are spheroidal masses, varying in size, having no cell wall, and containing one or more nuclei; there are about 7,000 to 10,000 of them in each cubic millimeter of blood. They differ much in appearance, and are divided into (1) small mononuclear leucocytes, or lymphocytes; (2) large mononuclear; (3) transitional; (4) polynuclear, or polymorphonuclear, or neutrophile, and (5) eosinophile. They are all more or less granular, particularly the last two varieties named. They are probably formed in the spleen, lymphatic glands, and lymphoid tissues. Their fate is uncertain; it has been asserted that they are converted into red blood cells; they play a part in the formation of fibrin ferment; they are sometimes converted into pus cells. Their functions are (1) to serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma.

3. *Fetal circulation:* "The blood returning from the placenta, after having received oxygen and being freed from carbonic acid, is carried by the umbilical vein to the under surface of the liver; here a portion of it passes through the ductus venosus into the ascending vena cava, while the remainder flows through the liver and passes into the vena cava by the hepatic veins. When the blood is emptied into the right auricle, it is directed by the Eustachian valve through the foramen ovale, into the left auricle, thence into the left ventricle, and so into the aorta and to all parts of the system. The venous blood returning from the head and upper extremities is emptied, by the superior vena cava, into the right auricle, from which it passes into the right ventricle, and thence into the pulmonary artery. Owing to the condition of the lung only a small portion flows through the pulmonary capillaries, the greater part passing through the ductus arteriosus, which opens into the aorta at a point below the origin of the carotid and subclavian arteries. The mixed blood now passes down the aorta to supply the lower extremities, but a portion of it is directed, by the hypogastric arteries, to the placenta, to be again oxygenated." (Brubaker.)

4. "The right auricle receives the venous blood as it returns from the tissues, and transmits it to the right ventricle. The function of the right ventricle is to pump the venous blood through the pulmonary arteries into the lung capillaries, where the venous blood becomes oxygenated. The oxygenated blood returns by the pulmonary veins to the left auricle and the arterial blood is then received into the left ventricle. The left ventricle pumps the arterial blood through the large arteries, the small arteries, and the arterioles into the systemic capillaries. The venous blood returns from the capillaries through the small veins into the larger veins, and the largest veins pour the blood back into the right auricle."

5. A cross section of the spinal cord in the mid-dorsal region shows that the cord is not quite circular in outline, but that the transverse diameter is greater than the anteroposterior diameter. The anterior median fissure is shallow, and the posterior median fissure is deep, extending beyond the center of the cord. The amount of gray matter is comparatively small, and both cornua are slender. The white matter is less than in the cervical region, but is still great in comparison with the gray matter. The central canal is not centrally placed, but is very much nearer to the anterior surface of the cord than to the posterior surface.

6. FIFTH PAIR OF CRANIAL NERVES. *Origin: Superficial,* from side of pons varolii; *deep,* from medulla, and floor of fourth ventricle. There are four ganglia in connection with this nerve; (1) The ophthalmic or lacrymal; (2) the sphenopalatine or Meckel's; (3) the otic; and (4) the submaxillary ganglion. *Distribution and Functions:* First, ophthalmic; sensory to anterior half of scalp, conjunctiva, and skin of upper eyelid, cornea, skin of nose, mucous membrane of nose, lacrymal gland. *Second,* superior maxillary; sensory to conjunctiva and skin of lower eyelid, nose, cheek, upper lip, palate, upper teeth, and alveolar processes. *Third,* inferior maxillary; sensory to external auditory meatus, side of head, mucous membrane of mouth, anterior two-thirds of tongue, lower lip, teeth, and alveolar processes of lower jaw. It is also motor to the muscles of mastication (temporal, masseter, two pterygoids), mylohyoid, and anterior belly of the digastric.

7. The *large intestine* consists of: Cecum or caput coli; ascending, transverse, and descending colon, with hepatic and splenic flexures; and rectum. Its structure resembles

that of the small intestine, but there are some differences. The transverse colon has a peritoneal covering, the other parts are only incompletely invested with peritoneum. The muscular coat shows its longitudinal fibers as three bands, which produce sacculations; to the large intestine are attached appendices epiploicæ. The mucous membrane has no villi, and is lined with columnar epithelium. The *chief function* of the large intestine is absorption, especially of water; it also hydrolyzes and digests and absorbs proteids under certain conditions.

8. The *functions of the liver* are: (1) the secretion of bile; (2) the formation and storage of glycogen; (3) the formation of urea and uric acid; (4) the manufacture of heat; (5) the formation of creatinin; (6) the production of antithrombin; (7) the conversion of poisonous and harmful into inert material; (8) it is also a reservoir for blood on its way to the heart.

9. "The kidney is a compound, tubular gland composed of microscopic tubules whose function it is to secrete from the blood those waste products which collectively constitute the urine. If the apex of each pyramid be examined with a lens, it will present a number of small orifices, which are the beginning of the uriniferous tubules. From this point the tubules pass outward in a straight but somewhat divergent manner toward the cortex, giving off at acute angles a number of branches. From the apex to the base of the pyramids they are known as the tubules of Bellini. In the cortical portion of the kidney each tubule becomes enlarged and twisted, and after pursuing an extremely convoluted course, turns backward into the medullary portion for some distance, forming the descending limb of Henle's loop; it then turns upon itself, forming the ascending limb of the loop, reenters the cortex, again expands, and finally terminates in a spheric enlargement known as *Müller's* or *Bowman's capsule*. Within this capsule is contained a small tuft of blood-vessels, constituting the *glomerulus*, or *Malpighian corpuscle*. Each tubule consists of a basement membrane lined by epithelium cells throughout its entire extent. The tubule and its contained epithelium vary in shape and size in different parts of its course. The termination of the convoluted tube consists of a little sac or capsule, which is ovoid in shape and measures about 1/200 of an inch. This capsule is lined by a layer of flattened epithelial cells, which is also reflected over the surface of the glomerulus. During the periods of secretory activity the blood-vessels of the glomerulus become filled with blood, so that the cavity of the sac is almost obliterated; after secretory activity the blood-vessels contract and the sac-cavity becomes enlarged. In that portion of the tubule lying between the capsule and Henle's loop the epithelial cells are cuboid in shape; in Henle's loop they are flattened, while in the remainder of the tubule they are cuboid and columnar." (Brubaker's *Physiology*.)

10. The skin is composed of a deep portion, the corium, derma, or true skin; and of a superficial portion, the epidermis or cuticle.

The *corium* makes up by far the greater part of the skin, and within it are the perspiratory glands, the sebaceous glands, the hairs, together with both blood and lymphatic vessels. The upper surface, where it joins the epidermis, is irregular, being composed of elevations—papillæ—and intervening depressions. In some of these papillæ are the tactile corpuscles, in which nerve-fibers end.

The *epidermis* is made up of a deep and a superficial layer. The deep layer (rete mucosum or rete Malpighii) covers the papillæ of the corium and fills the depressions between them. It is composed of cells, round or of different shapes due to pressure of continguous cells, the material of which they are composed yielding readily. It is in this layer that the pigment is deposited which characterizes the dark races. The superficial layer of the epidermis is composed of cells which are flat and dry or horny. (Raymond's *Physiology*.)

The *functions of the skin* are: Protection, excretion, secretion, regulation of the body temperature, absorption, sensation, special sense of touch, respiration.

### CHEMISTRY.

1. The *halogens* are: Fluorine: F., 19. Chlorine: Cl., 35.5. Bromine: Br., 80. Iodine: I., 127. They are called halogens because they combine with metals to produce salts, like sea-salt; the word halogen is derived from two Greek words denoting "sea-salt," and "to produce."

2. Morphine, dose 1/5 grain; codeine, dose ½ grain; and thebaine.

3. *Test for strychnine:* Inject a small quantity into a lymph pouch of a frog; violent tetanic spasms and opisthotonos will result.

*Treatment of overdose of strychnine:* Give the patient chloroform, by inhalation; or chloral hydrate. Wash out the stomach with solution of potassium permanganate.

4. Potassium iodide is made by saturating a solution of potassium hydroxide with iodine:

$$6KHO + 3I_2 = KIO_3 + 3H_2O + 5KI.$$

The formula of potassium iodide is KI.

5. Chemical formula of lunar caustic is $AgNO_3$. The antidote is sodium chloride.

6. Urine is composed of: Water; urea, uric acid, hippuric acid, xanthin, hypoxanthin, creatin, creatinin; sulphates, phosphates, and chlorides (of sodium, potassium, etc.); and pigments. The average daily amount of urea excreted is about 500 grains.

7. *Enzymes* are more or less hypothetical substances, produced by living cells, and having certain characteristic actions. Thus, they are capable of causing change in a large amount of material on which they exert their characteristic action, but they themselves remain unaltered. Most of them are destroyed by prolonged contact with alcohol. Each requires a certain reaction and a certain temperature in order to do its best work. Most of them are destroyed by a high temperature. Their *function* is various: Some hydrolyze starch; some saponify fats; some decompose proteids; some split up glucosides; some cause oxidation; some produce coagulation.

8. *Proteins* are substances of very complex composition and of unknown constitution; they constitute the greater part of animal and vegetable tissues. They all contain carbon, hydrogen, oxygen and nitrogen; some also contain sulphur, phosphorus, iron, or some other element. They are developed mainly from plants.

9. *Pyroxylin* is hexanitrocellulose; it is also called guncotton. It is obtained by dipping cotton in a cold mixture of one part of nitric acid and two parts of sulphuric acid, then washing and drying it.

10. $NaNO_3 + H_2SO_4 = NaHSO_4 + HNO_3$.

### MATERIA MEDICA.

1. An *aperient* is a mild purgative which produces moderate peristalsis and causes no irritation. *Example:* Sulphur.

2. *Vascular contractors* are agents which increase the contractile power of the blood-vessels, raise the blood-pressure, and diminish the flow of blood. They are used to stop hemorrhage and to alleviate inflammatory processes.

3. *Vascular dilators* are agents which produce dilatation of the peripheral blood vessels; they increase the rapidity of the circulation, relieve internal congestion, and tend to equalize the blood-pressure. The most useful are alcohol and ether.

4. A *solvent* is an agent capable of dissolving substances; as water, alcohol.

An *excipient* is a substance used as a vehicle for the administration of other drugs; as: acacia, tragacanth.

5. By the *physiological effect of a drug* is meant the influence which the drug exerts upon the various bodily organs or tissues in health.

6. The most powerful hydragogue cathartic is elaterin; dose, gr. 1/10.

7. Tincture of opium; ten minims equal one grain of opium. Camphorated tincture of opium; half an ounce contains about one grain of opium. Powder of ipecac and opium; ten grains contain one grain of opium.

8. "Applied to the skin in weak or moderately strong solutions, carbolic acid produces local anesthesia with a sensation of numbness, which lasts for several hours. Applied in concentrated form it is irritant and superficially escharotic, with burning pain of brief duration, and produces at the point of application a white spot, changing to red if the acid is soon removed. It does not vesicate, but if the application be prolonged a white eschar or slough results from coagulation of the albumin of the tissue, and this is bordered by a red zone of inflammation. Even a three per cent. aqueous solution, kept on a part for several days, has produced dry gangrene of the tissues." (Potter's *Materia Medica*, etc.)

9. If morphine is kept in solution for a long time, it may change into apomorphine.

10. Potassium iodide.

### THERAPEUTICS.

1. *Materia medica* is that branch of science which treats of medicinal remedies, their origin, composition, properties, action, etc. *Therapeutics* relates to the treatment of disease. It includes materia medica, surgery, diet, climate, nursing, electricity, and many other agencies.

2. *Empirical therapeutics* denotes the use of therapeutic agents for the sole reason that they have been found efficacious in previous similar cases.

*Rational therapeutics* denotes the use of therapeutic

agents founded on a knowledge of the pathological condition present in the patient, and the physiological action of the agent employed.

3. *Suggestive therapeutics* is the treatment of disease by means of suggestion.

4. Strychnine, or ammonium chloride, or atropine.

5 and 6. *Symptoms of carbolic acid poisoning:* Buccal mucous membrane is whitened and hardened; vomiting; burning pain in mouth, esophagus, and stomach; pulse and body temperature are lowered; the pupils are contracted; collapse, and finally death. The urine may become dark.

*Treatment:* Emetics, white of egg, sodium sulphate, stimulants. Alcohol is said to be antidotal.

7. Antidote for *arsenic,* freshly prepared solution of ferric hydroxide (chemical); for *opium,* tannic acid (chemical); for *copper,* potassium ferrocyanide (chemical); for *strychnine,* tannic acid (chemical).

8. Formaldehyde is liberated in the urine by hexamethylenamine. This is indicated as a urinary and intestinal disinfectant. It is used in cystitis, pyelitis, phosphaturia, and in typhoid fever.

9. Atropine sulphate, by hypodermic injection.

10. Lumbar puncture is made between the fourth and fifth lumbar vertebræ, the needle is left in place, and cerebrospinal fluid is allowed to escape (as much as will run freely). In case the lumbar puncture is made for diagnostic purposes only, about 5 c.c. should be withdrawn. A sterile syringe is filled with about 30 c.c. of the antimeningitis serum, is attached to the needle, and the injection is given. See SURGERY, question 4.

PATHOLOGY.

1. *Gangrene* is death of tissue *en masse. Varieties:* Dry, moist, direct, indirect, infective, metastatic.

2. "*Atrophy* may be simple or numerical. In the former kind, to which the term true atrophy might also be applied, the individual cells decrease in size without manifest disease; in the latter the cells are reduced in number, and are usually first altered by some form of degenerative disease, so that the process is not, strictly speaking, true atrophy. The parenchyma of organs suffers first and most characteristically, the connective tissues remaining unaffected or even undergoing hyperplasia. In true atrophy the cells may present no definite alteration, excepting perhaps slightly increased pigmentation. In some of the conditions generally described as atrophy the cells show degenerations of various forms such as cloudy swelling, coagulation-necrosis, fatty degeneration with vacuolization, and other gross alterations of structure. Secondary degenerative changes may occur in the connective tissues after the parenchyma-cells have become atrophic. Thus, after the physiological atrophy of the thymus-gland has occurred the connective tissues of the gland and of the surrounding parts become converted into fatty tissue. In other cases myxomatous change may be observed. Organs which have undergone atrophy are often quite irregular on the surface from unequal involvement of the different constituents. The consistency may be little changed or may be greatly reduced, particularly when some form of cellular degeneration is present. On the other hand, the organ may be hard and tough from secondary hyperplasia of the connective tissue. The capsule is generally wrinkled from the shrinkage of its contents, and secondary thickening is not unusual, especially in the heart and spleen. The color of the organ, like that of the individual cells, often becomes darker than normal and may be decidedly changed in brown atrophy. In cases of pressure-atrophy various distortions of the affected organ may be observed." (Stengel's *Pathology.*)

*Degeneration:* "Several abnormal substances may appear in the tissues as results of their degeneration, and, according as these substances are believed to be derived from the cell-protoplasm itself or to be merely deposits from the blood, the degenerative processes are divided into two groups: the metamorphoses or degenerations proper and the infiltrations. They differ essentially. In the metamorphoses the cell-protoplasm is gradually transformed into a new material. This process is often continued until complete destruction of the histological elements has taken place and all trace of the original structure is lost. In the earlier stages of the process function is impaired, in the latter it may be completely arrested. In the infiltrations the new material is not derived from the cell-protoplasm, but is deposited from the blood; there is an infiltration of a new substance. This is rarely followed by destruction of any of the histological elements; hence the structure of the tissue is much less altered than in the metamorphoses, and function is usually much less interfered with." (Green's *Pathology.*)

3. Metastatic extension of *sarcoma* is usually by the blood-vessels; of *carcinoma,* usually by the lymphatics.

4. Increased blood pressure is usually found in: Arteriosclerosis, chronic interstitial nephritis, eclampsia, uremia. The result may be cerebral hemorrhage.

5. The *pathological changes in pellagra* are neither definite nor constant. Atrophy of muscles, heart, liver, and pancreas has been found; the intestines may be ulcerated or contain parasites. The nervous system may show no changes, or there may be degenerative or sclerotic areas in the spinal cord; degeneration or round cell infiltration of some of the nerves may be present.

6. *Chronic nephritis* produces or is accompanied by: Cardiac hypertrophy, arteriosclerosis, enteritis, edema, uremia, and sometimes endocarditis, pericarditis, or pleurisy.

7. The principal parts involved in acute anterior poliomyelitis are: The ganglion cells in the anterior horns of the spinal cord, the neuraxons passing from these cells through the anterior roots, and the muscles over which these nerves have a trophic influence.

8. *Scarlet fever.* "Except in the hemorrhagic form, the skin after death shows no traces of the rash. There are no specific lesions. Those which occur in the internal organs are due partly to the fever and partly to infection with pus-organisms. The anatomical changes in the throat are those of simple inflammation, follicular tonsillitis, and, in extreme grades, of diphtheroid angina. In severe cases there is intense lymphadenitis and much inflammatory edema of the tissues of the neck, which may go on to suppuration, or even to gangrene. Streptococci are found abundantly in the glands and in the foci of suppuration. The lymph glands and the lymphoid tissue may show hyperplasia, and the spleen, liver, and other organs may be the seat of widespread focal necroses. Endocarditis and pericarditis are not frequent. Myocardial changes are less common. Nephritis is an important complication." (From Osler's *Practice.*)

9. *Chronic gastritis.* "The appearance of the mucous membrane varies greatly. In the milder cases the surface is more or less irregular and granular, and is covered with mucous exudate. The color may be grayish, but in cases in which passive congestion has preceded the development of gastritis it is often slate-colored from pigmentation. Microscopically there may be found mucous degeneration of the cylindrical epithelium of the tubules, and desquamation and not rarely proliferation of the secretory epithelium in the fundus of the glands. The glands may be considerably dilated and filled with mucous exudate and desquamated cells. The interglandular tissues are infiltrated, and may be thickened by the formation of new connective tissue; the same process may involve the sub-mucous coat. The blood-vessels of the latter are often greatly dilated and their walls may be thickened. In the later stages the glands may undergo progressive atrophy, the epithelium disappearing almost entirely and the lumen of the gland becoming less and less distinct. Coincidently with these changes, and to some extent causing them, there is fibrous overgrowth of the interglandular tissues." (Stengel's *Pathology.*)

10. *Scorbutus.* "The blood is dark and fluid, and its composition deranged with diminution in the potassium salts. Anemia is present, but there is no increase in the white blood cells. The structure of the blood-vessels is altered, allowing spontaneous hemorrhages into the skin, muscles, joints, and internal organs and from the mucous membranes. There is swelling and ulceration of the gums often resulting in loss of the teeth. Ulcers of the ileum and colon may be encountered. The spleen is enlarged and soft, and the viscera are affected with parenchymatous changes." (Hughes' *Practice of Medicine.*)

(*To be continued*)

---

**Human and Bovine Bacilli in Bone Tuberculosis in Children.**—J. Fraser states that the all-important point revealed by his investigation is the fact that a large proportion of bone and joint tuberculosis occurring in children in Edinburgh owes its origin to infection by the bovine bacillus. The bovine bacillus is introduced into the system practically by one route only, that of ingestion, and the medium with which it is ingested is cow's milk. In those case in which the human bacillus was present, a considerable proportion showed a definite history of pulmonary tuberculosis affecting a co-resident, and every fact went to prove that the infection had been a direct one from patient to child. A complete distinction can be drawn between human and bovine bacilli, and the distinction is best secured by subjecting the organism to a series of tests as detailed by the author. The subject is one which ought to be investigated in a series of different localities. It is possible that the *locus* may be a factor in the explanation of the difference between the above results and those of other observers.—*Journal of Experimental Medicine.*

# Medicolegal Notes.

**Promise to Pay for Medical Services Furnished to Another.**—In an action for professional services for curing another under a verbal agreement with the defendant to pay therefor, and on his credit the defendant denied that he made such an agreement, but admitted that he did on behalf of his father, with the knowledge of the plaintiff that he was acting for his father, engage the plaintiff to attend his brother who was sick of smallpox, and he also admitted that he himself agreed with the plaintiff to pay him for two visits to his brother at $10 a visit and that he did pay for those two visits. It was held that the question whether the services were rendered under the agreement alleged was for the jury, and if they found in the affirmative the defendant would be liable to the plaintiff to pay therefor, notwithstanding any subsequent promise of any other person to pay the plaintiff for such services, which promise would not alone be sufficient to affect the right of the plaintiff to proceed against the defendant upon such special promise.—Knowles v. Massey, Delaware Superior Court, 81 Att., 470.
